The original researches carried out by Mr. Pycraft were concerned chiefly with the anatomy of birds. His first paper, published in the *Ibis* in 1895, described and discussed the arrangement of the feathers in the Tinamous, and in 1898 he contributed a memoir on the feathering of the owls to the *Transactions of the Linnean Society*. Between 1898 and 1907 he wrote a valuable series of nine papers on the osteology of birds published in the *Proceedings of the Zoological Society*, and in 1900 he discussed the morphology and phylogeny of the Palæognathæ and Neognathæ in an extensive memoir in the *Transactions* of the same Society.

Mr. Pycraft also began to take much interest in the variations of the human skull, and in 1915 he proposed to substitute for the Frankfort base-line another line which passed wholly through the cranium avoiding the upper part of the face. This proved to be not generally acceptable, and he returned to the subject in a paper in *Man* in 1925. He wrote several accounts of human skulls, the most noteworthy being his description of the Boskop fossil from South Africa in the *Journal of the Royal Anthropological Institute* of 1913, and a description of the Rhodesian fossil skull in a British Museum volume in 1928. He took part in several discussions on the Piltdown skull, and in 1917 published in *Science Progress* an account of the lower jaw which pointed out its differences from the jaw of an ape.

Mr. Pycraft was also a prolific writer of popular books and articles on natural history, which brought him a large correspondence and not infrequently led to the discovery of new facts. His first popular books were the small "Stories of Bird Life", "Fish Life" and "Reptile Life", published by Newnes in London between 1900 and 1905. "A History of Birds", a more serious work, appeared in 1910, and his "Birds of Great Britain" followed in 1934. His volumes on the "Infancy of Animals", "The Courtship of Animals" (1913) and "Camouflage in Nature" (1925) are especially readable and contain original observations. His weekly article in the *Illustrated London News* was a much-appreciated feature of this paper for many years, and attracted wide attention.

In all his writings Mr. Pycraft showed great interest in the possible mode of evolution of the various structures and habits which he described, and an address on "Some New Aspects of Evolution" which he delivered to the Norfolk and Norwich Naturalists' Society in 1935 was reprinted in the annual report of the Smithsonian Institution, Washington, in the following year. His style was sometimes forceful, for when he had formed an opinion he could not readily be persuaded that it might be mistaken; but he had a versatile mind and was always inspiring. He is mourned by a large circle of friends who learned the more to appreciate him the closer they were associated with him.

A. S. WOODWARD.

WE regret to announce the following deaths:

Prof. Charles Cohen, formerly of the Brussels Pasteur Institute, aged sixty-one.

Dr. R. L. Ditmars, the distinguished herpetologist, formerly curator of mammals and reptiles in New York Zoological Park, on May 12, aged sixty-five.

Dr. Bernhard Fischer-Wasels, professor of morbid anatomy at Frankfort-on-Main, president of the German Pathological Society and editor of the *Frankfurter Zeitschrift für Pathologie*, aged sixty-five.

Sir James Larmor, F.R.S., formerly Lucasian professor of mathematics in the University of Cambridge, on May 19, aged eighty-four.

Prof. B. Malinowski, professor of anthropology in Yale University, formerly University professor of anthropology in the London School of Economics, on May 16, aged fifty-eight.

Dr. C. Hart Merriam, founder in 1885 and until 1910 chief of the United States Bureau of Biological Survey, now known as the Fish and Wild Life Service, on March 19, aged eighty-six.

Dr. John Miller, director of aircraft production (factories), formerly chief engineer, London and North-Eastern Railway (N.E. Area), on May 16.

The Rev. T. E. R. Phillips, a past-president of the Royal Astronomical Society and of the British Astronomical Association, on May 13, aged seventy-four.

Dr. G. G. Stoney, F.R.S., who for many years was associated with C. A. Parsons and Co. Ltd., particularly in connexion with the development of the steam turbine, on May 15, aged seventy-eight.

Prof. G. A. Witherington, formerly professor of mathematics in the Royal Naval College, Greenwich, on May 1, aged sixty-nine.

Prof. W. J. Young, professor of biochemistry in the University of Melbourne, aged sixty-three.

NEWS and VIEWS

World Mineral Resources and Post-War Needs

In the fourth clause of the Atlantic Charter, Mr. Roosevelt and Mr. Churchill state "that they will endeavour, with due respect for their existing obligations, to further enjoyment by all States, great or small, victor or vanquished, of access, on equal terms, to the trade and to the raw materials of the world which are necessary for their economic prosperity". The Division for the Social and International Relations of Science of the British Association is therefore arranging a conference on "Raw Materials and Industrial Needs: Mineral Resources and Outlook", to be held in London at or about the end of July. As Sir Richard Gregory, president of the Association, pointed out in submitting the proposal for such a conference, the world's natural resources—both organic and inorganic—are much too large a subject to be dealt with in a single conference, but a survey of the present position of minerals of industrial importance, with suggestions for further investigations into their geographical distributions and research into the production of substitutes, will show the close contact between science and fundamental national and international problems. The Conference will indeed be similar to a joint meeting of the Sections of Geology, Geography, Physics and Chemistry at an annual assembly of the British Association, and its papers will be of the nature of contributions to a report upon the distribution, output and industrial uses of the chief mineral deposits of the world. Such energy resources as solid, liquid and gaseous fuels belong to a class of their own, and the facts relating to them have been brought before a number of World Power Conferences. Whatever is known about the nature, distribution and uses of minerals in the earth's crust has been gained by scientific inquiry, and the knowledge is international in origin and scope. By presenting the chief facts as to natural resources of minerals and their geographical control, such a conference can do much to promote recognition of the interdependence of nations and the need for collaboration between them.

Scientific Workers of the Argentine

During last March, Prof. E. D. Adrian, professor of physiology in the University of Cambridge, paid a visit to the Argentine at the invitation of the Argentine National Academy of Medicine. He was welcomed with much cordiality and was frequently assured of the sympathy of Argentine medical men and scientific workers for the Allied cause. Towards the end of his visit, Prof. Adrian was asked to receive a deputation from the Comisión Sanitaria Argentina de Ayvda a las Democracias (Health Committee to Aid Democratic Countries). This deputation asked Prof. Adrian to convey a message of solidarity to members of the medical profession and scientific men in Great Britain. The Committee said that the example set by British men of science working in their laboratories and clinics, holding congresses even in war-time to promote the application of scientific discovery to the progress of mankind, and arranging the co-ordination of the scientific work of Great Britain, the U.S.S.R. and the United States, strengthens their faith in the triumph of democracy through science. This very cordial message from the Argentine will be received with much satisfaction by scientific workers in Great Britain, who will be encouraged to pursue the course they have set for themselves in helping to rid the world of totalitarianism.

Illuminating Engineering Society

At the annual general meeting of the Illuminating Engineering Society on May 12, Mr. W. J. Jones (president) was able to present an encouraging record for the past session. A feature has been the further development of centres and groups, of which there are now eleven, and which are expected to do useful work in studying the lighting requirements of special local industries. The position in regard to the Society's work on A.R.P. lighting, undertaken jointly with the Ministry of Home Security, has for the time become stabilized, but a number of committees are now exploring various aspects of lighting in relation to after-war reconstruction. The "Recommended Values of Illumination" put forward by the Society (I.E.S. Code) has been adopted by the Ministry of Supply, the Admiralty and the Ministry of Aircraft Production, in applying the Factories (Standards of Lighting) Regulations (1941). Many members of the Society are engaged in the task of designing lighting installations for factories engaged on national work. The Society in 1940 initiated the practice of conferring fellowship on those of its members having the requisite technical qualifications. The number of fellows created is now 96—rather less than ten per cent of the membership of the Society. The new president for the forthcoming session is Mr. R. O. Ackerley.

The Illuminating Engineering Society made a practice, in the years preceding the War, of inviting an eminent expert from abroad to deliver an address on the occasion of each annual meeting. This practice is no longer possible in the present circumstances, but its own members have filled the gap. The lecturer on May 12 was Mr. G. H. Wilson, who took for his subject "Street Lighting: Past, Present and Future". Mr. Wilson remarked that the period 1928–38 was one of great technical progress. An outstanding event in 1928 was the erection of fifty model lighting installations illustrating the eight classes of the British standard specification. This led to a recognition of the importance of road surface brightness as a factor in relation to visibility. During the ten-year period two new sources, the sodium and mercury vapour lamps, were introduced. Their unusual spectra raised new problems and their shape and size made necessary considerable changes in the design of lanterns. Attention was also devoted to the problem of the siting of posts, which was discussed in the report of the departmental committee appointed by the Ministry of Transport appointed in 1934. After referring briefly to lessons to be learned from our experience of the low orders of illumination available during the present black-out, Mr. Wilson reviewed after-war problems. He pointed out the possibilities of the new fluorescent lamps, expressing the belief that technical resources are enormous. The future of street lighting, he affirmed, depends largely on the extent to which the scientific attitude of mind is employed in the application of the achievements of research—for example, in connexion with bold experiments in town planning.

Fluorescent Lighting

A paper on this subject, read recently by L. J. Davies, H. R. Ruff and W. J. Scott before the Institution of Electrical Engineers in London, gives a brief history of fluorescent lighting and follows this by a description of a typical mains-voltage tubular fluorescent lamp and the principles of its operation. The new fluorescent lamp combines the high efficiency of the straight electric discharge lamp, with much of the convenience of operation of the incandescent lamp, while possessing, in addition, special characteristics of low brightness, exceptional colour-rendering power, and comparative absence of radiant heat. The 200/250-v., 80-watt lamp and its auxiliaries, marketed in Great Britain in March 1940 to improve factory lighting in blackout conditions, are described in detail and the characteristics and components of the complete unit are explained. This lamp is 5 ft. long and 1½ in. in diameter, taking 0·8 amp. at a lamp voltage of 115; its nominal luminous efficiency is 35 lumens/watt and its mean brightness is 3·3 candles/sq. in. Its high electric power/light conversion ratio is examined together with the conventions whereby these are assessed. The paper concentrates attention upon the practical features of the lamp, but gives a sufficient description of the physics involved to promote an appreciation of both the present characteristics and future importance of this type of light source. The authors conclude that the lamp is satisfactorily fulfilling a present industrial need, and that its quality has been so greatly appreciated that it is undoubtedly the forerunner of a new series of lighting lamps.

Industry in Scotland

In the discussion in committee in the House of Commons on May 12 on the estimates for the Scottish Home Department, Mr. T. Johnston, Secretary of State for Scotland, gave a survey of industrial development in Scotland since 1918. He referred to the advisory committee on Scottish industry which has been set up, and expressed the hope that by its means the industrial aftermath in Scotland of 1914–18, due to concentration on heavy industries for export, will be avoided. In the course of the discussion, Sir John Graham Kerr put in a plea for the development of a variety of small light industries. The industrial belt of Scotland has grown in its present position because the sources of power are close at hand. Industry tends to drift to the more populous parts of the country—in Scotland to the south—and one way of stopping this drift is to carry power all over the country. The transport of power is of vital importance. In the form of coal and oil, subject to road or rail transport, power is only distributed with difficulty and at relatively high cost. The newer method of distribution of power through an electric grid might have a tremendous influence on Scotland and its industries, for, by these means, the site of industry is no longer tied to the source of power, and the feeding of small units becomes feasible.

Austrian Scientific Workers in Great Britain

An Association of Austrian Engineers, Chemists and Scientific Workers in Great Britain has recently been formed. The main activities of the Association will be to assist members in their professional work and interests, to represent them with the authorities, to promote contact and relations with British colleagues and to form a link with British scientific and technical institutions. Lectures, courses and discussions will be held and will give opportunities for the exchange of views and to discuss matters of mutual interest. It is hoped that the Association may assure that better use is made of the knowledge and abilities of Austrian engineers, chemists and scientific workers who are anxious to assist in the war effort. The acting chairman of the Association is Dr. F. Ehrenfest-Egger; inquiries should be sent to the honorary secretary, Mrs. K. Hilfreich, 133 Hatherley Court, London, W.2. Lectures are being given on the first Monday of each month. Every Monday, commencing June 1, at 7 p.m., a club-room will be open for members of the Association at the Austrian Centre, 69 Eton Avenue, N.W.3, where there will be opportunities to read technical periodicals and to meet other colleagues.

A Relic of Dr. John Dee

The sale by Messrs. Sotheby of an interesting relic of the mathematician and astrologer Dr. John Dee, who was patronized by Queen Elizabeth, was recorded in *The Times* of May 5. The relic is a gold disk 3½ in. in diameter weighing 1 oz. 4 dwt. 5 gr., bearing the London date letter for 1589 and engraved with a diagram of the "Vision of the Four Castles" which appeared to his medium Edward Kelley, on the morning of June 20, 1584, at a house in St. Stephen's Street, Cracow, where the two men were staying. The diagram is reproduced in "A True and Faithful Relation of what passed for many Years between Dr. John Dee . . . and some Spirits" published in 1659 by Dr. Meric Casaubon. The disk was bought by the British Museum for £230.

Institution of Electrical Engineers Awards

THE Council of the Institution of Electrical Engineers has made the following awards of premiums for papers read during the session 1941–42, or accepted for publication: *Institution Premium* to Mr. J. M. Meek; *Ayrton Premium* to Mr. J. S. Forrest; *Fahie Premium* to Dr. W. G. Radley and Mr. E. P. G. Wright; *John Hopkinson Premium* to Dr. A. L. Williams and Mr. L. E. Thompson; *Kelvin Premium* to Mr. E. Colin Cherry; *Overseas Premium* to Prof. K. Aston and Mr. M. V. Kesava Rao; *Extra Premiums* to Dr. A. H. M. Arnold, Mr. G. W. Bowdler, Messrs. G. W. Bowdler and W. G. Standring, Mr. R. Davis, Dr. H. D. Einhorn and Prof. B. L. Goodlet, Dr. Hackett and Mr. A. M. Thomas, Mr. E. A. Richards, Mr. V. Sia, Messrs. R. C. Woods and A. S. MacDonald; *Installations Section Premiums* to Messrs. L. J. Davies, H. R. Ruff and W. J. Scott (Crompton Premium), Mr. R. Grierson; *Meter and Instrument Section Premiums* to Messrs. E. A. Burton, J. S. Forrest and T. R. Warren (Silvanus Thompson Premium), Mr. D. J. Bolton; *Transmission Section Premiums* to Mr. J. W. Leach (Sebastian de Ferranti Premium), Messrs. W. Casson and F. H. Birch; *Wireless Section Premiums* to Mr. O. S. Puckle (Duddell Premium), Dr. D. C. Espley and Mr. D. O. Walter (Ambrose Fleming Premium), Messrs. J. E. Thwaites and F. J. M. Laver.

Earthquake in Ecuador

REPORTS have been received from Guayaquil, the chief port of Ecuador, that a severe earthquake took place in the interior on the night of May 13–14. Guayaquil itself was severely shaken for some 60 seconds according to human perception, and buildings collapsed. It is estimated that about sixty people lost their lives. Mr. J. J. Shaw's seismograph at West Bromwich recorded a severe earthquake at 2h. 25m. 52s. U.T. on May 14. Further news is awaited. It will be recalled (NATURE, Feb. 11, 1939, p. 238) that several earthquakes shook a considerable area in Ecuador including the towns of Vallechillos and Quito on the night of February 1, 1939. On that occasion the volcano Cotopaxi erupted.

Earthquakes Registered at Kew

Two strong distant earthquakes have recently been recorded at Kew Observatory. The first, on April 8, 1942, began recording on the vertical component at 15h. 53m. 58s. U.T. impulsively, and on the N and E components at the same time P was emergent. The shock probably originated some 11,000 km. distant, at maximum attained an amplitude of 410 μ at Kew, and finished recording at 19h. 20m. U.T. The second, on April 13, began recording impulsively on all three components at 07h. 55m. 48s. U.T. from an epicentral distance of 6,130 km., attained a maximum amplitude of 94 μ and finished recording at 10h. 00m. U.T. All readings are tentative.

Between April 15 and May 5 eighteen earthquakes were registered by the seismographs at Kew Observatory. All these shocks gave rise to small amplitudes with the exception of the earthquake of April 20. This began recording at 08h. 52m. 40s. U.T. and finished recording at 10h. 25m. U.T. The interpretation of this record is at present tentative, though an epicentral distance of 125° is possible.

The Ipswich Man

THE skeletal remains known as the Ipswich man, which have been housed at the Royal College of Surgeons, London, since they were discovered in Bolton and Co's brickfield, Ipswich, in 1911, have now, through the instrumentality of Mr. Reid Moir, and the kindness of the president and Council of the College, been presented to the Ipswich Museum. Since 1911 a great deal has been discovered regarding the age of these remains, which were thought originally to be older than the Upper Chalky Boulder Clay—a deposit of one of the major glaciations of East Anglia. It now seems clear that the skeleton is referable to one of the prehistoric floors situated in the slopes of the adjacent valley, and examples of flint implements, etc., found in these floors are exhibited with the human bones in the entrance hall of the Ipswich Museum. Though all the geological and archæological aspects of this matter are not yet completely understood, it is highly probable that the Ipswich man lived in the earlier part of Upper Palæolithic times, and is of considerable antiquity.

Announcements

PROF. E. H. ALTON, registrar and professor of classics in Trinity College, Dublin, who represented the College in the Dail from 1923 until 1937, when the University representation was abolished and he was elected to the Irish Senate, has been appointed provost of the College in succession to the late Dr. W. E. Thrift.

MR. HARRY BREARLEY, the well-known steelmaker of Sheffield, has been elected to honorary membership of the Iron and Steel Institute. Mr. Brearley's recently published autobiography was reviewed in NATURE of April 11, p. 397.

THE British Standards Institution has been recognized by the Government as the sole organization for the issue, in consultation with any Government, professional or industrial bodies concerned, of standards having a national application. In regard to the preparation and issue of codes of practice for building and civil engineering work, the Minister of Works and Buildings is making special arrangements by the appointment of a representative committee with which the Institution is co-operating.

As from the commencement of next session, the name of the Meter and Instrument Section of the Institution of Electrical Engineers will be altered to "Measurements Section". The Section will include within its scope all matters relating to electrical measurement and control, the design and application of the apparatus, and the materials employed in connexion with them.

A DISCUSSION on "Soviet Metallurgy", arranged by the Faculty of Science, Marx House, will be held at the London School of Hygiene and Tropical Medicine, Keppel Street, W.C.1, on May 28 at 7 p.m. The discussion will be based on a paper by Mr. Tom Barker, who took a leading part in the creation of the great Kuzbas Metallurgical Combine in Siberia. Tickets of admission, including a copy of Mr. Barker's paper, can be obtained from Marx House, Clerkenwell Green, London, E.C.1, price 2*s*.

Cosmic Rays and Magnetic Storms

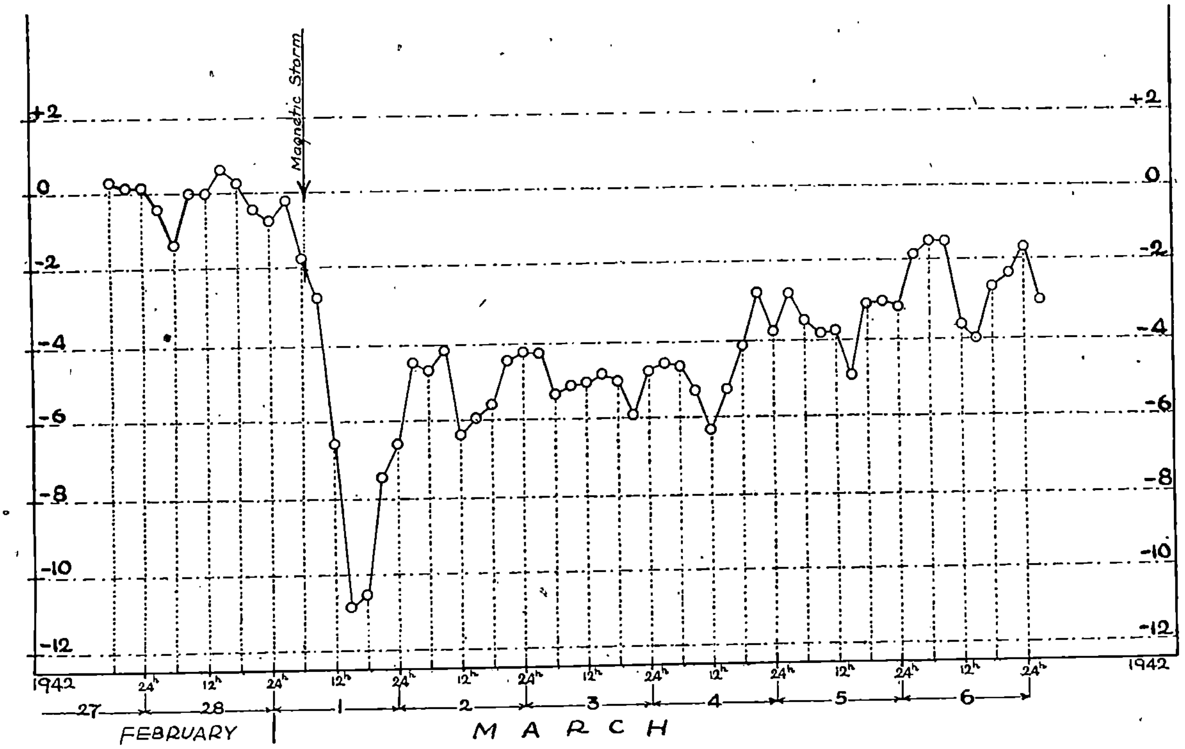
HOURLY records of the intensity of cosmic rays have been made during the past year. The apparatus used consisted of a battery of Geiger counters registering about 25,000 threefold coincidences each hour. The circuit used gave a negligibly small number of casual coincidences. No absorbing screens were used, but preliminary experiments with lead showed that the thickness of the counter walls was sufficient to cut out all radioactive rays and the very soft cosmic rays. To count such a rapid rate of coincidences without loss, a Wynn-Williams' scale-of-two counter[1] was used. For this circuit the resolving time is so reduced that, at the counting rate of 400 per minute, the number of particles which is missed is not more than one per thousand. The number of pulses recorded by the telephone counter is photographed automatically every hour.

The whole apparatus was prepared in the Physical Laboratories at the University of Manchester, and the observations are being made in a room at the top of the Imperial College of Science, South Kensington.

The observations began in February 1941, but the photographic recording started only in April. The first phenomenon to which attention was given was the so-called temperature effect of cosmic rays, not only because of its importance in itself, but also so as to be able to eliminate this influence from the observations and thus to establish more accurately the other time variations. A detailed account of the results of the work will be given elsewhere. It will be shown that the changes from day to day in cosmic rays, when corrected for changes in atmospheric absorption, are well correlated with the variations in height of the atmospheric layer of given pressure at which mesons are supposed to be formed. This is consistent with Blackett's explanation on the basis of the instability of the meson.

When this effect is eliminated from the observations, then the well-known world-wide changes appear which are associated with the disturbances of the terrestrial magnetic field. These changes are being studied in detail.

In this letter an account is given of the remarkable changes of cosmic ray intensity associated with the magnetic storm of March 1, 1941. The figure shows the observed time variation from February 27 to March 6. The decrease of nearly 12 per cent on March 1 is certainly unusually great, and, so far as is known to us, is the largest variation of this kind so far recorded.



PERCENTAGE DEFICIENCIES OF COSMIC RAYS DURING FEB. 27–MARCH 6.

The points on the diagram represent the mean value of the cosmic ray intensity during a period of three hours. The scale is in percentages from the normal value. The cosmic ray disturbance began shortly before the onset of the magnetic storm. From information kindly given by the Royal Observatory, the latter began at 7h. 27m. on March 1. Allowing for the statistical fluctuations (± 0·36 per cent for the three-hour period), it appears that the cosmic rays disturbance began about one hour earlier. The storm subsided rapidly after 1 a.m. on March 1 and finished three hours later. After the first rapid recovery of about half the initial drop, which occurred within twenty hours of the onset, the recovery was very slow and was not complete by the sixth day.

It is remarkable that the magnetic storm was not so intense as some others which have been accompanied by a less violent disturbance in cosmic rays. The extreme range in the horizontal magnetic force H was $512\,\gamma$, equivalent to less than 3 per cent of the H value. Nevertheless, it appears that the bright eruption which began to be observed on the sun 19h. 27m. earlier was one of the most extensive recorded, lasted for an unusually long time and produced a much larger magnetic effect than usual. Also a special feature of the storm was a series of 27 giant pulsations in H and V which lasted from 15h. 5m. to 17h. 3m. on March 1, and are, it seems, unique in the Abinger records. It was just in this interval when the number of cosmic particles reached its lowest value. The mean of the two-hourly observations centred at 16h. and 17h. represents a decrease in this number of 12·0 ± 0·44 per cent.

From the record of this and other storms, it seems clear that, at any rate in these latitudes, there is no simple proportionality between geomagnetic and cosmic rays disturbances.

Dispersion of Cellulose Strands in Cell Walls

In a recent letter in NATURE[1] Prof. Frey-Wyssling directs attention to the importance in cell wall studies of the *angular dispersion* of the constituent cellulose micelles and refers to my papers as ignoring this property. Cell wall physics is a study in which there is already much controversy, and it seems therefore a pity to give the impression of a difference of opinion where none actually exists. The question centres round the desirability of taking into account not only the 'parallel' texture said to be typical of fibres but also the so-called 'dispersed' or 'reticular' texture present in some other cell types. So far as I am concerned, the difference between 'parallel' and 'dispersed' textures is one of degree only and actually, far from taking ". . . only parallel textures into account . . .", I have yet to investigate a single cell in which I am convinced that this texture does occur in anything like a strict sense. In some fibres[2] and wood cells[3], for example, where Frey-Wyssling himself supports parallel texture, and in some collenchyma[4], my collaborators and I have shown that the angular dispersion of the cellulose micelles about the extinction direction may be considerable and is probably of importance in explaining certain optical properties of the wall. These latter papers have apparently not been available to Prof. Frey-Wyssling since his citations of my papers cease in 1939.

In the paper from which he quotes, however, I made the first suggestion, later applied also to the conifer tracheid[3], that certain optical properties are to be explained in terms of the angular dispersion of the cellulose matrix. In cross-section the walls of some of the cells referred to (vessels of some ring-porous trees) show optical discontinuities, and concerning the explanation of this fact I remarked: ". . . the observed phenomena may be accounted for either by a variation in chain direction from layer to layer, by a variation in chemical nature, by 'a change in the *dispersion* of a single direction', by a variation in the amount of cellulose present in the crystalline phase, etc. Any one of these possible causes 'may be accepted only when the others have been ruled out'." The sections quoted by Prof. Frey-Wyssling (enclosed in single inverted commas) are therefore misleading. The full quotation, and even more strongly the sense of the whole paper, makes it abundantly clear that here I am questioning not the existence of dispersion or even of changes in dispersion but whether these can explain the phenomena under review. In fact the purpose of this paragraph was to emphasize what I have repeatedly said elsewhere—that the *angular dispersion* of the cellulose in a wall should not be overlooked in studying its optical properties.

In several places[6] I have directed attention to the dangers involved in the interpretation of optical properties, and particularly of extinction directions, when unsupported by other evidence and it comes therefore as a surprise to find myself indicted for failing to observe my own precepts. On the other hand, while it is clear that the cellulose of most, if not all, cell types is to be thought of as 'dispersed' rather than 'parallel' in the strict sense, it seems to me a natural and legitimate simplification, in making preliminary calculations such as I have presented, to take the extinction direction of a wall of the 'dispersed' type as a hypothetical unique 'cellulose chain direction'. In most cases the modifications to be expected in adding the dispersion around the extinction direction to the resulting figures are of secondary importance only, and may be considered at a later date as the opportunity and necessity arise. Admittedly, there are some cases where this assumption cannot safely be made—cases where the dispersion itself is of vital importance—and one of these I propose to examine elsewhere in the near future, but generally in geometrical considerations of growth problems where I have used this simplification I maintain that it is fully justified.

With the statement of Prof. Frey-Wyssling that the dispersion can be measured most readily from the X-ray photograph I am, of course, in complete agreement. I myself have hitherto used no method other than this, but of the available indirect methods I would prefer the fluorescence staining method of Morey[7] to the chlorzinc iodide method of Frey-Wyssling since the latter technique introduces possible changes in dispersion on swelling. I would like, however, to point out further that Prof. Frey-Wyssling is in error when he implies that no X-ray photographs are available of single cell walls. A photograph has already been published of the X-ray diagram of an oak vessel[5] and of what corresponds to single walls of a conifer tracheid, and in each of these photographs the angular dispersion can be measured approximately. Under some conditions, moreover, the dispersion can be detected and measured in some cell types even though bundles of cells rather than individual walls are photographed[4].

There is, therefore, no fundamental difference between Prof. Frey-Wyssling's attitude and mine concerning the 'dispersed' texture. The 'reticular' texture figured so often by Frey-Wyssling is, however, of a somewhat different type and I must confess some hesitation in accepting this as a possibility as it stands. That there occurs in latex vessels and in most cells with primary walls a high degree of dispersion is well established, but this by no means suggests that the cellulose complex is reticular.

Effect of Certain Chemotherapeutic Agents on Experimental Eye Lesions produced by *Staphylococcus aureus*

THE difficulty of producing uniform staphylococcal lesions of the cornea in the rabbit, for the purpose of estimating the value of therapeutic measures, has long been recognized[1] although Brown and Pugh[2] succeeded in producing a fairly satisfactory ulcer by using a strain found after many trials.

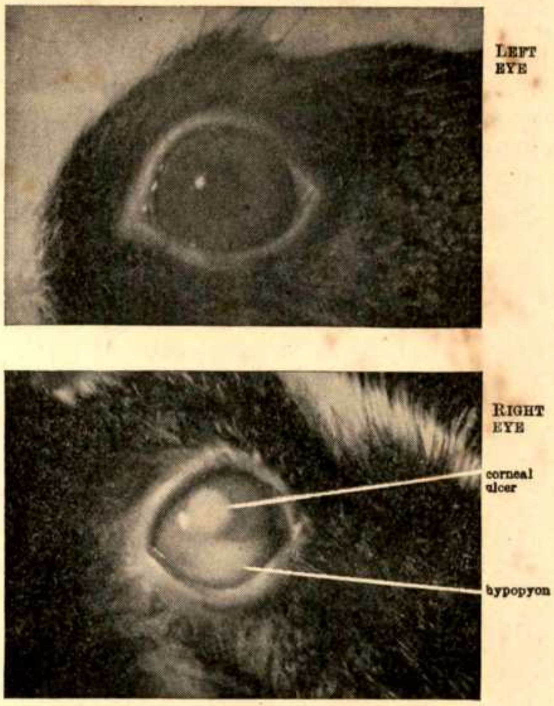
In the following experiments eight coagulase positive strains of *Staphylococcus aureus*, obtained from human lesions, were tried in preliminary tests on rabbits' eyes, and the one found to be the most virulent was used as it consistently produced a lesion. The lesions, however, were too acute and rapidly destructive when an undiluted culture was injected into the cornea, and therefore, after a number of preliminary trials, the following technique was evolved.

A 24-hour culture in broth was diluted with saline to contain 1,500 organisms per c.c., and this was injected into the cornea to make a small bleb under the epithelium. In each rabbit both eyes were so injected, and great care was taken to make these initial inoculations as equal as possible. In each animal one eye was treated with the appropriate chemotherapeutic agent, while the other eye was similarly treated with saline.

The first treatment was applied one hour after inoculation, and the treatment was usually continued at hourly intervals for the next forty-eight hours, and thereafter at less frequent intervals.

Lesions involving ulceration of the cornea invariably developed in the control eyes, and in 90 per cent of cases this was associated with development of hypopyon. In some 75 per cent of cases the ulcers were large and resulted in either extensive corneal scarring or gross destruction of the eye with or without perforation.

The lesions developed rapidly and by the end of forty-eight hours after inoculation the ulcers were already, as a rule, moderately severe and associated with hypopyon and considerable iritis.



CONDITION OF EYES OF RABBIT 494 ON SECOND DAY AFTER INOCULATION.
Left eye, treated with penicillin; right eye, control.

The following chemotherapeutic preparations were used: (1) sodium sulphacetamide (this was supplied to us as a 30 per cent solution, and was used either undiluted or diluted with saline to a 10 per cent or a 2·5 per cent solution); (2) a 15 per cent solution of solubilized sulphathiazole (sulphathiazole sodium formaldehyde sulphoxylate); and (3) solutions containing penicillin, prepared by extracting from fluid culture with amyl acetate and re-extracting into water, as described by Florey *et al.*[3]. When assayed by the methods described by these authors the solution produced an area of bacteriostasis 21–23 mm. in diameter, when tested against *Staphylococcus aureus*.

The results obtained with these preparations are shown in the accompanying table. Penicillin proved

EFFECTS OF VARIOUS TREATMENTS ON EXPERIMENTAL STAPHYLOCOCCAL LESIONS

The main subdivision has been drawn between slight and moderate, since the 'slight' lesions left scars which were small and localized and would not have seriously interfered with vision, whereas the 'moderate', and of course the more severe lesions, produced scarring which was considerably more extensive, and which would have seriously interfered with the function of the eye. The very severe lesions involved gross destruction of the eye. The figures represent the percentage of eyes, in any one group, showing the particular type of lesion.

Treatment	Lesion produced					No. of animals
	None or trace %	Slight %	Moderate %	Severe %	Very severe %	
Control	0	8	38	38	16	13
	8			92		
Penicillin	31	46	15	8	0	
	77			23		
Control	0	31	44	6	19	16
	31			69		
30% sod. sulphacetamide	19	56	19	0	6	
	75			25		
Control	0	33	33	22	11	9
	33			66		
15% sulphathiazole	11	44	33	11	0	
	55			44		

to be the most effective in the treatment of these staphylococcal lesions. It is probable that still better results will be produced with more concentrated solutions of penicillin. The result in one animal (494) is illustrated in the accompanying figure.

Sodium sulphacetamide (30 per cent) produced quite obvious beneficial effects.

Because of its known value against staphylococci, we expected very satisfactory results with the concentrated solution of sulphathiazole, but they were unfortunately disappointing.

Weaker concentrations of sodium sulphacetamide were tried in small groups of animals. The results suggest that a 10 per cent solution may perhaps be as effective as the 30 per cent solution, but the 2·5 per cent solution produced only slight benefit in the treatment of these lesions.

The preliminary reports of Florey *et. al.*[3] have already suggested that penicillin may be effective in the treatment of eye lesions. Our experimental results support this conclusion, and also offer evidence that sodium sulphacetamide may be of value in the local treatment of staphylococcal lesions of the human eye.

We should like to thank Dr. Oag, of the Department of Bacteriology, University of Edinburgh, for his advice and for supplying the cultures and dilutions used in these experiments. Mrs. MacNaughtan, of the Department of Bacteriology, University of Edinburgh, very kindly supplied us with penicillin solution. We are indebted to Dr. Prescott of Burroughs, Wellcome and Co. for the preparation of the solubilized sulphathiazole and to Mr. Edwards of British Schering, Ltd., for the supply of sodium sulphacetamide (albucid soluble).

We are grateful to the W. H. Ross Foundation (Scotland) for the Study and Prevention of Blindness, which defrayed the expenses of this investigation.

Microbial Synthesis and Autolysis in the Digestive Tract of Herbivora

Both the rumen in ruminant and the cæcum in non-ruminant Herbivora support an abundant iodophile microflora : that is, an association of taxonomically diverse species exhibiting, in consequence of the deposition within them of bacterial starch or granulose, the common characteristic of giving a blue reaction with iodine.

I have established by direct microscopic observation that the iodophile micro-organisms make their appearance on the adoption by the young animal of a vegetable diet, progressively displacing the aniodophile species prevalent in the early phases of milk-feeding ; and, furthermore, that they play a determinant role in the decomposition of starch, pectins and cellulose [1,2,3].

Thus the decomposition of these substances in the rumen or cæcum is accompanied by the deposition within the micro-organisms of an iodophile polysaccharide. The opinion has been advanced, moreover, that the products of synthesis as well as the initial products of decomposition may be utilized by the host animal[3,4,5,6]. In conformance with this opinion is the fact that very few iodophile micro-organisms are found in the fæces[3,6]. It can be demonstrated that several agents may be concerned in their elimination. Thus *in vitro* experiments on centrifuged suspensions of iodophile micro-organisms from the rumen of cattle have shown that they are not acted upon by peptic and only slowly affected by commercial tryptic preparations. Observations, however, on fresh rumen contents demonstrated that they are ingested and digested in large numbers by the ciliates present (Ophryoscolecidæ and Isotrichidæ), thus confirming Westphal's results with *in vitro* cultures of rumen protozoa[7]. It was found, moreover, that the ciliates, unlike the iodophile micro-organisms, were readily acted upon by enzyme preparations. Similarly, examination of post-mortem material showed that in the abomasum the majority of the rumen Protozoa had been digested (cow and sheep). In the cæcum of the horse a digestion of bacteria by ciliates (Cycloposthidæ, Paraisotrichidæ, Butschlidæ, etc.) had also been recorded[6]. In the guinea pig, however, the Entodiniomorpha are not represented and the small flagellates present (Hexamita, Trichomonas, etc.) do not play an important part in the removal of bacteria[5]. Finally, in the adult rabbit, Protozoa may be altogether absent[4]. In these cases other agencies must be invoked to account for the observed elimination of iodophile micro-organisms. An intensive action of digestive enzymes is precluded by the position of the cæcum and colon. It had been conjectured, therefore, that in these conditions bacterial autolysis might play an important part[6]. This hypothesis has now been tested as follows :

Cæcal contents of a guinea pig were removed and a portion suspended in 10 per cent formalin (control). The remaining portion was diluted with saline saturated with chloroform and divided into two fractions. One of these was heated to 100° C. for 2 min. Both were incubated at 37° C. for 12 hr. The formalized control showed an abundant disintegration of starch grains which were entirely surrounded by iodophile micro-organisms. In the boiled fraction the iodine reaction of the iodophile micro-organisms was unchanged, whereas in the unboiled fraction it had entirely disappeared. Since the reaction of the grains was unimpaired the absence of free amylase could be inferred. The changes witnessed were, therefore, attributed to autolysis. Identical results were obtained in parallel experiments performed with rumen contents of cattle.

It is clear, therefore :

(*a*) That several agencies may co-operate to a varying degree in different Herbivora in the elimination of the iodophile micro-organisms, namely :

(1) Ingestion and digestion by Protozoa.
(2) Action of digestive enzymes.
(3) Bacterial autolysis.

(*b*) That the mode of elimination in ruminants is more complex than in non-ruminants.

(*c*) That in the simplest instance elimination may be effected by bacterial autolysis alone.

Any effort, therefore, to elucidate the complex problems concerned in the effective utilization of a particular diet must inevitably take account of the interadjustment of the processes enumerated, that is, of the actual mode of transference of the available polysaccharides from the vegetable materials ingested to the tissues of the animal. No mention has been made in this communication of the protein syntheses integral to the maintenance of a microbial population in the cæcum or rumen; nor of the initial nitrogen sources from which they may be able to proceed. A detailed study of some microbiological aspects of the problem is, however, now being made in close collaboration with the biochemical investigation of *in vitro* incubations of rumen contents in progress at the Hannah Dairy Research Institute[3,8].

Spore Dispersal in the Mucorales

THE problem of spore dispersal presented in my last communication[1] is now partially solved, as a result of spore-blowing experiments and the observation of cultures grown in cemented glass cells with coverslip surfaces.

The chief fact which emerges is that the Mucor sporangium is primarily a water dispersal mechanism, and that Mucor spores, for the most part, become airborne only after preliminary separation in water, and then chiefly on the surface of soil dust particles and hyphal fragments.

The sporangial membrane in Mucors breaks up and eventually disappears in contact with water. In Mucors with thin walls, usually described as 'diffluent' (for example, *M. hiemalis*), this process is rapid, and if the sporangium remains untouched in moist air it gives place to a conspicuous sporangial drop. The stalk on losing turgidity collapses and usually brings the drop against a solid surface, whereupon it spreads out rapidly owing to surface tension. The word 'burst' is inappropriate to describe this process. On drying down the spore masses remain firmly stuck together with mucilage which, however, is readily dissolved and the spores separated in water.

Growing on organic matter in soil the sporangiophores can be seen to form a network linking the soil particles, against which the sporangia are inevitably brought into contact at some stage, with the presumed result that the spores are dispersed by the soil water when present.

Spore-blowing experiments on this type of Mucor show them to be complete *spore retainers* in air. The function of the sporangiophore is thus seen to be that of ensuring some preliminary dispersal of the spore masses, rather than that of raising the sporangium into the air. Its sensitiveness to light in the early stages of growth may also have the effect of counteracting the down-washing of water, and raising the spore masses so as to keep them in the upper layers of the soil, where both aeration and organic matter provide more favourable conditions for the growth of Mucors.

However, when air-dried soil, which has been sterilized and then soaked in a suspension of spores of *Mucor hiemalis*, is subjected to gentle blowing, many colonies are obtained, some of which arise from visibly single spores, but the majority from soil particles, and natural soils also yield scattered colonies of diffluent-walled Mucors. The occurrence of air-borne infections by Mucors of this type is thus explained, and also their frequent presence in dust.

Some species, however, notably *M. rouxianus*, exhibit a subsidiary form of air dispersal, in that the old dry mycelial network is extremely brittle, and when blown upon fragments, yielding scattered colonies each of which is found to arise from a spore mass, or even a single spore, attached to a hyphal fragment. This is referred to as *hyphal spore dispersal*.

Mucor racemosus also fragments in this way, dispersing chlamydospores as well as attached sporangiospores. A few spore masses, without hyphæ, are also dispersed, and the stalks do not collapse so completely, so that some direct air dispersal is possible. Here the wall survives longer in contact with water, and the spores have been seen to pass out into a superficial drop. The sporangial drops are less conspicuous, as surviving pieces of wall may render them relatively opaque. Probably most of the Mucors with thick ('fragmenting') walls are of this type, which remains chiefly water-dispersed.

Absidia glauca is a *spore-mass-shedder* with relatively little hyphal dispersal. Despite such adaptations to air dispersal as stoloniferous growth, rigid sporangiophores, and a columella which collapses into a cup, liberating the whole spore mass, it forms sporangial drops, scatters no single spores in air, and seems to be readily water-dispersed. It is thus intermediate in type.

Rhizopus nigricans, however, exhibits advanced adaptation to air dispersal. The sporangiophores, borne aloft on 'stolons' and firmly 'rooted' on their substrate, remain rigid when dry, and the collapse of the columella into a bell-shaped cap exposes the spores to air movements for long periods. Such sporangiophores, grown in a glass cell in 1939, are still erect and capable of shedding viable spores after three years. The rough angular spores are not easily wetted, and do not 'clump' closely in water, so that they dry out rapidly, and are not stuck together in mucilage. This type, however, sheds no spores when moist, but broadcasts spore masses of varying size, and single spores, when quite dry. It is therefore called a *dried-spore-shedder*.

Finally, in conidial types such as Cunninghamella we have *spore shedders* which scatter spore masses from the fresh, moist colony, and vast numbers of single spores from the dry, and are comparable in efficiency of air dispersal with many Hyphomycetes.

The Mucorales are thus brought into closer relationship with the other groups from which they have been somewhat isolated. Once it is realized that the Mucor sporangium is a water-dispersal mechanism, it can bear some comparison with that of the soil Oomycetes, especially in those species which liberate akinetes, and at the same time the various conidial forms, some of them approaching those of the Plectomycetes, become intelligible as adaptations to air dispersal.

SEA WAVES: THEIR GROWTH AND SUBSIDENCE

By P. J. H. UNNA

THE effect of tidal streams on swell was discussed in NATURE of February 21, p. 219, the standard for comparison being the slack-water state. Estimates depended on the fact that, in swell, waves retain their identities as individuals. But wind-forced waves cannot do so, even when there is no change in stream, because, with speed proportional to root of length, their periods lengthen as they grow—see below—and in so far as this affects the issue the arguments for swell may not hold good. But stream, tidal or otherwise, can also influence rate of growth, for which no slack-water standard is available, the laws of growth being still unknown. It is therefore necessary to improvise.

It seems that any system of wind-forced waves consists of at least three series: the primary and most conspicuous waves, the smaller secondary ones which ride upon them, and the long low waves[1,2], more akin to swell, that are masked by the primaries. It may be assumed that, under stabilized conditions, steady wind of given strength gives rise to primary waves of given average length and height, according to fetch and to strength and direction, or absence, of stream. But the only data available are two independent sets of observations, which, when combined, give figures for primary waves due to the strongest winds ordinarily met with. These figures are merely tentative, but suffice to show the general trend, and to illustrate the principles involved.

First, there are Stevenson's equations[3], intended to give greatest wave height according to fetch:

$H_{max.} = 1{\cdot}5F^{\frac{1}{2}} + 2{\cdot}5 - F^{\frac{1}{4}}$ for fetches from 1 to 39 miles,

$H_{max.} = 1{\cdot}5F^{\frac{1}{2}}$ for fetches from 40 to 120 miles, F being fetch in miles. Secondly, taking Wilton's[4] theoretical limit of 0·13 for steepness as applicable to new-born waves, the more reliable recorded measurements, including many of those summarized by Gaillard[5], indicate that for wave-lengths up to 400 ft. the greatest steepness ordinarily met with in the open may be expressed as:

$$S_{max.} = (7{\cdot}5 + 0{\cdot}3H)^{-1},$$

$$\text{that is, } L = 7{\cdot}5H_{max.} + 0{\cdot}3(H_{max.})^2.$$

There is no guarantee that all the measurements on which these equations are based relate to slack water, as will be assumed here. And the equations will be taken as the history of growth of a definite wave system under steady wind, although the strongest winds over short fetches are unlikely to persist over long ones. The following equations result:

$$\frac{dP}{dF} = 9H(2{\cdot}5L^{\frac{1}{2}} + 0{\cdot}15L^{-\frac{1}{2}}H^2)\,(0{\cdot}75F^{-\frac{1}{2}} - 0{\cdot}25F^{-\frac{3}{4}}) \text{ up to 39 miles,}$$

$$\frac{dP}{dF} = 25L^{\frac{1}{2}} + 1{\cdot}5L^{-\frac{1}{2}}H^2 \text{ from 40 to 120 miles,}$$

P $(=EG)$ being power, that is, energy per sq. ft. of water surface multiplied by its speed to leeward. The resulting values are as in the table below.

F	H	L	$S = \frac{H}{L}$	$\frac{dP}{dF}$	Hours before stability of regime	$\frac{d\,(EL)}{dF}$	Waves lost, % per mile of fetch
1	3·0	25	0·120	173	½	935	8·7
4	4·1	35	0·114	162	1½	1,040	4·0
7	4·8	43	0·112	165	2	1,200	2·8
10	5·5	50	0·110	175	3	1,350	2·1
15	6·3	59	0·107	183	4	1,550	1·5
20	7·1	69	0·103	197	5	1,800	1·2
30	8·4	83	0·101	211	6½	2,150	0·9
40	9·5	98	0·097	(244)	8	(2,700)	0·8
50	10·6	113	0·094	282	9½	3,350	0·65
100	15·0	180	0·083	360	16	5,450	0·35
(200)	21	290	0·07		(25½)		(0·2)
(300)	26	400	0·065		(34)		(0·13)
(400)	30	500	0·06		(41)		(0·1)

The figures for dP/dF only relate to power effectively used in raising the primary waves. More is required for the other series, viscosity, turbulence, breaking, and to give leeway to the water near the surface. Nevertheless, they indicate that the wind acts more efficiently as the waves lengthen, and so, except at quite an early stage, by pressure rather than by friction, the area of application of the pressure speeding up as the waves move faster. Later, well beyond the limit of Stevenson's equations, diminution in steepness and in relative speed of wind and waves will cause the pressure to get less, and dP/dF to do the same.

The figures for time show how long the wind has to blow before the sea attains a steady maximum for a given fetch. They are based on the speed of the energy of the primaries.

EL, the total energy of a wave, per foot of crest, tends to concentrate near the crest just before breaking, and should therefore be an index of striking force against a breakwater. Values are given for $d(EL)/dF$ to show how, with steady wind, an extra mile added to a long fetch increases maximum striking force much more than when added to a short one. They are based on the derived expressions,

$(60H^2 + 4{\cdot}8H^3 + 16LH)\,(0{\cdot}75F^{-\frac{1}{2}} - 0{\cdot}25F^{-\frac{3}{4}})$ for short fetches,

$(60H^2 + 4{\cdot}8H^3 + 16LH) \times 1{\cdot}125H^{-1}$ for longer fetches.

Owing to lengthening of period, when waves increase in length from L_1 to L_2, one wave in every $\sqrt{L_2} \div (\sqrt{L_2} - \sqrt{L_1})$ has to disappear. In other words, one wave in every $2L.\frac{dF}{dL} + 1$ vanishes in each mile of fetch. The figures given for percentage loss show that the waves become more permanent with greater fetch, and presumably they then behave more like swell with change of stream. However, it is with these longer waves that stream has least effect on swell.

But stream may have consequences which do not arise with swell, for not only may it affect rate of growth, but also it may alter effective fetch. For example, when there is a local wind in the open, and so not blowing off a weather shore, speed over the ground becomes irrelevant, and yet stream may modify the fetch. Travel of the centre of a cyclonic disturbance is an analogous case. It increases fetch in one semicircle, by mere coincidence the one called 'dangerous' for quite a different reason, and reduces it in the other[6]. The speed of the centre in relation to that of the wave energy is the relevant factor.

Consideration of the effect of stream on rate of growth raises the rather puzzling problem of the hairpin bend. A river takes a hairpin bend, and the wind blows up one reach. Alternatively, it may be blowing up an arm of the sea with a narrow entrance, up the Solent from Hurst would be a case in point. Given, say, a 3-knot weather-going stream, the waves will fail to stem the tide until they attain a 5-ft. length, and their energy will fail to do so until they become 20 ft. long. Presumably waves do form near the weather shore when it starts to blow, but it looks as if they must be soon dispersed by breaking. The solution may be that those which form to leeward, and so in their early life are independent of speed over the ground, attain the lengths necessary for survival before they are swept back to the weather shore. In that case there should be waves of appreciable length where there is almost inappreciable fetch, after the wind has been blowing long enough for the conditions to be stabilized. It would be interesting to know what actually does happen.

But assuming that a stable regime has been attained, it is possible to roughly estimate the change in the demand for wind energy, and so the surplus available for increasing the sea, that a weather-going stream entails. Wave power over the ground is $E(G + C)$, C being stream in ft./sec., and negative for weather going. Let E_1G_1 apply to a given position, and E_2G_2 to another position a mile to leeward. The increase in wave power within that distance, that is, over a strip of water a mile long and a foot wide, will be $E_2G_2 - E_1G_1$ in slack water, and $E_2G_2 - E_1G_1 + C(E_2 - E_1)$ with stream C. That would only be strictly correct if the wind could be so adjusted that E_2 and G_2 might retain their slack-water values. Then $C(E_2 - E_1)$ would be the change which C entails in the demand for power, but it may also be taken as a rough estimate of the surplus available for increasing the sea when the stream has made to the weather without change in wind, a surplus additional to any due to greater speed of wind over water. To put this in another way, $\frac{d(EC)}{dF} = 16HC.\frac{dH}{dF} = 18C$ ft.-lb. per sq. ft. per sec. per mile, for Stevenson's highest waves with long fetches. The corresponding expression for short fetches would be $(18 + 34F^{-\frac{1}{2}} - 18F^{-\frac{1}{4}} - 10F^{-\frac{3}{4}})C$, giving $24C$, $19C$, $17{\cdot}5C$, $16{\cdot}8C$, $16{\cdot}3C$, $16C$, $15{\cdot}8C$ for the fetches in the table.

To take an example, the value of $18C$ for a 3-knot stream is 90, a constant surplus for weather going, and deficiency for lee going, stream comprised in the increasing slack water figures for dP/dF for the longer fetches in the table. Thus, as with swell, stream seems to have less proportionate effect on longer waves; and from the way in which the sea steepens when the stream turns to the weather, it looks as if the surplus is used in heightening rather than in lengthening them, and so in intensifying rather than in speeding up their energy. But this line of reasoning for the case in which a weather shore has to be taken into account has obvious defects, and it is only put forward in the hope that someone may be able to explain what really happens.

Now as to subsidence. The rate at which swell subsides owing to the viscosity of the water can scarcely be measured, but it has been calculated by Stokes[7], who, taking as examples waves 2 in. and 240 ft. long, has shown that it is much slower for the longer waves. Unfortunately, his formula gives the daily loss in height for the 240-ft. waves as only ½ per cent, and this seems much too small. In fact, a steepish swell only 100 ft. long should subside into an almost flat calm after a couple of days, whereas by formula it would only lose a tenth of its height a week. The probability is that other effects preponderate. Thus a short sea is generally local, and always so in narrow waters. Therefore the tail of its energy will soon pass on, and leave a calm behind. Again, waves lose height because their energy only travels half as fast as they do, and the shorter waves will lose height more quickly on this account. Compare two hypothetical swells, with 6,000 waves, 400 ft. and 100 ft. in length. They will cover 400 and 100 miles to start with. The middle waves of each will start to lose height, for the reason mentioned, when they have travelled through these distances, that is, after 15 and 7½ hours, as the case may be.

The modulus of viscosity is based on frictional action between layers shearing one over the other. On the other hand, water movement under wave action involves two-dimensional distortion, what were elementary cubes in calm being distorted, approximately, from upright to horizontal oblongs, cubical form being passed midway. If the work done against viscosity were proportional to the linear distortion of the cubes, the loss in wave height per second would be absolute, and not a percentage one, and proportional to $L^{-\frac{1}{2}}$, while the distance through which the waves would have to travel before they completely flatten down would be proportional to LH. That seems more in accordance with ordinary experience.

Perhaps an actual example will be more convincing. The period of the surf on the Guinea Coast, 10–12 sec., is about double the ordinary period of waves in the Straits of Dover. The surf probably originates in energy that has travelled from the Southern Ocean, a journey of at least a week, while hours rather than days would be the measure of the time of calming in the Straits.

But to return to the original question of length and height in relation to wind and fetch. Determination of the empirical laws should go some way towards solving the problems that surround wind-forced waves. Measurements taken at lee shores with various but preferably small exposures, during steady winds of various strengths, might give some clues, and they could easily be made where the conditions are suitable. In any event, waves affect so many things, ships—breakwaters, erosion and littoral drift—that further knowledge as to their behaviour can scarcely fail to pay.

NEW SEISMOGRAPH STATION AT LOGAN, UTAH

THE installation of a seismograph at Utah State Agricultural College was made possible through a gift from the estate of the late Thomas E. Oldham, an English-born resident of Logan, who died in 1938 ("The Oldham Seismograph station at Utah State Agricultural College, Logan, Utah", by J. Stewart Williams, *Bull. Seis. Soc. Amer.*, 32, No. 1, January, 1942). The name is a very happy one in view of the history of seismology, though the late Thomas E. Oldham of Utah bears no known relationship to Thomas Oldham of the Geological Survey of India (1816–1878), and R. D. Oldham his son (1858–1936), who first recognized the longitudinal and transverse character of the two types of preliminary waves of an earthquake.

The seismograph room is in the basement of the main college building, the approximate geographical location being latitude 41° 45′ N., longitude 111° 47′ W. The station is equipped with two horizontal-component Wood-Anderson seismographs bought with the gift, and an accelerograph installed by the United States Coast and Geodetic Survey. The seismometers are mounted on concrete blocks 28 cm. high, keyed into the surface of a pier, resting in well-cemented gravels of the Bonneville delta, and standing at a height of 4,772·3 ft. above sea-level. Installation of the accelerograph was completed in July 1939 and the Wood-Anderson instruments began operation on January 26, 1940. Since October 1, 1940, all seismograms have been checked by the United States Coast and Geodetic Survey, and the results will be published in the monthly seismographic report.

The north-south seismometer has a static magnification of 716·8, the east-west seismometer one of 697·9. The period for both is maintained at 6·0 seconds, the damping ratio at 20 : 1. The recording drum has so far been run at 15 mm./m. The seismometers are in protective coverings which are also provided with water cans in an attempt to eliminate temperature variations near the instruments. The accelerograph, lent and maintained by the United States Coast and Geodetic Survey, is a No. *M*-45, with a 12-in. recorder, and has three components.

The site appears to be a particularly happy one, especially for the accelerographs, since Utah appears to be the most seismically active of the Rocky Mountain States. This latter may be related to the zone of faulting that marks the eastern margin of the Great Basin. One centre of activity has been in Washington and Iron Counties, adjacent to the Hurricane fault, and another centre lies in Sevier County between the Tushar and Sevier faults. Nearly one third of the earthquakes of Utah have occurred close to the Wasatch fault.

FORTHCOMING EVENTS

(Meetings marked with an asterisk are open to the public)

Wednesday, May 27

Physical Society (Colour Group) (at the Royal Photographic Society, 16 Princes Gate, London, S.W.7), at 2.30 p.m.—Discussion on "The Relative Merits of Spectrophotometry and Colorimetry" (to be opened by Miss Dorothy L. Tilleard).

Institute of Chemistry (London and South Eastern Counties Section) (at 30 Russell Square, London, W.C.1), at 6 p.m.—Dr. H. Baines: "Recent Advances in Photographic Theory".

Thursday, May 28

British Psychological Society (Industrial Section) (at the National Institute of Industrial Psychology, Aldwych House, Aldwych, London, W.C.2), at 1.20 p.m.—Miss May Smith: "Fatigue, a Revision of Past and Survey of Present Problems".

Friday, May 29

Royal Institution of Great Britain (at 21 Albemarle Street, London, W.1), at 5.15 p.m.—Mr. Seton Gordon: "Wild Life in the Western Highlands".*

British Institution of Radio Engineers (London Section) (at the Federation of British Industries, 21 Tothill Street, London, S.W.1), at 7 p.m.—Mr. O. S. Puckle: "Time Bases".*

Institute of Physics (Manchester and District Branch) (in the Physics Department, University of Manchester), at 7 p.m.—Dr. J. McG. Bruckshaw: "Physics in the Search for Oil".*

Saturday, May 30

Nutrition Society (at the London School of Hygiene and Tropical Medicine, Keppel Street, London, W.C.1), at 11 a.m.—Conference on "Problems of Collective Feeding in War-time".

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Metallurgist for research work in connexion with problems attending colliery wire ropes and other coal-mining appliances—The Chief Executive Officer, Safety in Mines Research Laboratories, Portobello Street, Sheffield 1 (May 29).

Speech Therapist (woman)—The Director of Education, Education Offices, Woodlands Road, Middlesbrough (May 30).

Teacher of Mathematics and a Teacher of Physics—The Principal, South-West Essex Technical College and School of Art, Forest Road, Walthamstow, London, E.17 (May 30).

Lecturer in Science—The Principal, Domestic Science Training College, Knighton Fields, Leicester (May 31).

Electrical Engineer and Manager—The Town Clerk, Town Hall, St. Helens, Lancs. (endorsed 'Appointment of Electrical Engineer and Manager') (June 1.)

Senior Lecturer (man or woman) in the Science Department of the City of Leeds Training College, with special qualifications in Biology—The Director of Education, Education Offices, Leeds 1 (June 1).

Chief Laboratory Steward—The Principal, Technical College, Doncaster.

Senior Woman Lecturer in Biology—The Principal, Southlands Training College (London), at Highbury, Atlantic Road, Weston-super-Mare.

Mistress to take charge of the General Science Work—The Headmistress, Day Technical School for Girls, Fort Pitt, Chatham.

REPLANNING GREAT BRITAIN

THE satisfaction which was given by Lord Reith in his statement in the House of Lords on February 11, announcing the establishment of the Ministry of Works and Planning, to be endowed with the necessary powers derived in part from the existing Town and Country Planning Acts and in part from forthcoming legislation, including that designed to give effect to the recommendations of the Uthwatt Committee, passed into concern in view of succeeding ministerial changes and the absence of the promised statement from the Government. That concern has been largely dispelled by the statement made by Lord Portal in the House of Lords on April 21. Following on Mr. Bevin's address to the opening session of the Emergency Committee of the International Labour Organisation, and succeeded by Mr. Oliver Lyttelton's broadcast on April 26, it afforded reassuring evidence not only that the policy outlined by Lord Reith is unchanged, but also that the Government is facing the problems of the post-war world, and that some at least of its members fully realize the contribution a reconstruction policy can make to the winning of the War.

Lord Portal said that Lord Reith's statement made in February still stands. The Bill already introduced in the Commons, the second reading of which was moved by Mr. H. Strauss on April 29, was the first step in the creation of a Ministry, the objective of which would be to secure the right use of land for all purposes. It would be the duty of the Minister to see that policies in regard to agriculture, transport, etc., are properly co-ordinated. Legislation has been drafted after consultation with Mr. Justice Uthwatt and Lord Justice Scott, whose reports should be available in the near future.

Lord Portal said that he fully agreed with what was said in a previous debate about the excessive number of planning authorities. Considerable reduction has been effected by the voluntary combination of local authorities, and it is the policy of the Government not only to reduce the number by planning over wide areas but also to accelerate the process. Area officers have already been selected to assist by collaboration with the local authorities, whom they will also aid in their planning work, keeping the local authorities informed of the national considerations which must be taken into account, and the Ministry of what is taking place in each area.

Referring to the need for speeding up the working of the Town and Country Planning Act, Lord Portal said that no planning would be complete which does not provide for the preservation of extensive areas of great natural beauty, and especially the coast-line. Protection of national parks and coasts from ill-considered building must be fully examined. He said he is working in the closest collaboration with the Paymaster-General on this and other questions ; and with regard to the personnel of planning, directly the War is over, it will be essential to have the building industry organized to cope with the vast amount of work with which it will have to deal. A well-balanced programme for new houses, schools and other buildings and repairs, and for having the men available quickly to do the work, is already well advanced. Demobilization both from the Services and the munition factories has already received attention, and a long-term programme of training on demobilization is an essential factor which requires to be thought out.

Lord Portal indicated that he appreciates the importance of the location of industry and of co-ordinating the contributions to post-war reconstruction from different Government departments. The services of the advisory panel of experts set up by Lord Reith will still be available, and a Bill will be introduced to take over the powers of the 1932 Planning Act.

This Bill, which received its second reading on April 29, is admittedly only a very small step, and little enthusiasm could be discerned for it in the House of Commons debate. It provides for the transfer to the Minister of Works and Planning of all the existing functions of the Commissioners of Works and the Commissioners of Public Works in Ireland and of the Town and Country Planning functions of the Ministry of Health. The exact extent of the transfer of powers, like the precise relations between the Minister of Works and Planning and the Post-master-General, is not quite clear.

The meagre advance represented by the new Bill is apparent from the valuable report issued by the Reconstruction Committee of the Royal Institute of British Architects on "Legislation affecting Town and Country Planning"*. The debate on the Minister of Works and Planning Bill is in fact calculated to arouse rather than dispel misgivings as to the Government's intention, if only from the indications it affords that the delays in the appearance of the reports of the Uthwatt and Scott Committees are due not so much to the Committees as to the diversion of their members to other duties by the Government itself. Yet until these reports have appeared, the essential legislation is deferred, and opportunities are in fact being lost and obstacles being allowed to accumulate through dilatoriness and inaction.

The Reconstruction Committee of the Royal Institute of British Architects, after a survey in some detail of present legislation affecting town and country planning, such as the Town and Country Planning Act 1932, the Local Government Act 1933, the Restriction of Ribbon Development Act 1935, the Trunk Roads Act 1936, and Acts affecting private street works and general building control, recommends first the establishment forthwith of one national planning authority with a Minister to lay down the main lines of the national plan, including trunk roads and other means of transport, assisted by expert planners, research and advisory committees as required. The establishment of regional officers of the Ministry to prepare and extend the national plan to meet the needs of the region and a grouping of the local authorities in each region for planning purposes in sub-regions or groups as required for efficient planning are next recommended. In regard to control, the report recommends that planning control should include all land, including the preservation of land essential for agriculture and public reservations for any purpose, with no exemptions for Government lands, railways or other public utilities or for agricultural buildings.

As recommended by the Uthwatt Committee, the existing control of all development by licence should be extended for a fixed period until the constructive proposals of the national plan are worked out. Such control by licence should include control over the extension of existing industry as well as the location of new industry, and a limit of not more than twenty years should be fixed for the continuation of non-conforming uses. Detailed improvements should be effected in town-planning legislation on lines which have already been recommended, subject to the adjustments necessary to fit in with the national and regional administration and to the employment of a competent architect.

On the financial side, the report recommends simplification of the acquisition of land for public purposes, with the price of acquisition stabilized at a figure not exceeding the value at March 1939, and a similar stabilization of the price of land acquisition between private persons. In each district there should be a local improvement and open spaces fund, provided partly by Government grant, partly by a limited local rate and partly by contributions payable by all developers, thus providing for essential widenings, open-space reservations and proper maintenance. Besides this, the necessary finance should be available on a national basis for the preparation and implementing of the national plan. This must cover the encouragement of agriculture and proper marketing facilities and the provision of rural water supply and electricity; the encouragement of the proper location of industry and the provision of new industrial centres, the building of suitable new towns and trading estates, including the utilization of mineral and natural resources, and the extension of public utility services; the improvement of transport, including road, rail, water and air transport; and the reservation of national and regional spaces for recreation, including national parks and coastal reserves, regional open spaces and playing fields, and the preservation of buildings of national or historic importance.

The arguments and recommendations of this report are well underlined by Mr. Roland Pumphrey in his pamphlet in the Rebuilding Britain Series*. Dealing with the relation of industry to reconstruction and particularly with the tendencies to migration to be found in industry, he gives an admirable indication of the way in which those tendencies can best be turned to account. He focuses attention on the problems which require attention, the questions, such as the probability of the drift of industries and services into the south-east of Great Britain and to the Midlands being resumed after the War, the influence of evacuation on the growth of a more decentralized metropolitan type, and the means of securing a better distribution of town and country life without injury to agriculture and amenities, to which answers must be sought before policy is crystallized.

---

* Legislation affecting Town and Country Planning. (London: Royal Institute of British Architects.)

* Industry and Town Planning. By Roland Pumphrey. Pp. 36. Rebuilding Britain Series, No. 6. (London: Faber and Faber, Ltd.) 1s. net.

Mr. Pumphrey stresses the importance of preparing now, by wise legislation, by judicious placing of war-factories, war-houses and hutments, by research and by a constant watchfulness over changing conditions, and by uplifting public opinion, for the tasks which lie ahead; there must be a dynamic outlook. Everything must be related to the ever-changing panorama of human and material events. Secondly, he makes the point that British democracy should not attempt to embrace and control the destinies of the people by a comprehensive planning of all social and economic life. Rather should it, by wise governance and by devolving the necessary legislation and control, ensure the ways and means to a free co-operation for the development of the whole nation, in which industry and agriculture, town and countryside, shall find a harmony and identity of interests.

The core of the pamphlet, in fact, lies in Mr. Pumphrey's conclusion that industrial and town and country planning interests should join forces in providing an outline, based not only on the common requirements of industries, towns, transport and communications, but also with equal regard to the richest agricultural lands and scenic amenities. The details of location and environment can be left to sub-regional planning councils, but the striking of a balance between the requirements of the various parts of the country requires the advice and guidance of a central planning authority, exercising powers within a general outline of territorial lay-out and location as affecting the nation at large. Aided by an industrial advisory commission, a national planning Ministry might seek further to prepare public opinion for coming tasks by setting up well-equipped regional information bureaux in all principal centres, providing a tangible link between the Ministry and industry and the community.

In the debate in the House of Commons on the Planning Bill, both Mr. Strauss and Sir William Jowitt showed in their speeches that the Government's objective is to secure the right use of the land of Britain for all purposes; thus the various aspects outlined by the Reconstruction Committee of the Royal Institute of British Architects and in Mr. Roland Pumphrey's pamphlet are evidently under review. What is principally at issue at the moment is the excessive slowness of advance. While no exception can fairly be taken to Sir William Jowitt's contention that we should await the reports of the Scott and Uthwatt Committees before attempting legislation, Mr. Greenwood's suggestion that all members of these committees are being overloaded with other work of less importance is not reassuring. At the least it indicates that the Government does not view the matter with the same sense of urgency and importance that it is viewed by the country at large.

There can be no question that already a vast amount of the necessary knowledge has already been acquired, and that what is now essential is action, particularly legislative action, so that the fuller plans can be worked out in readiness, and power exercised where necessary to prevent further obstacles developing either during or immediately after the War. Moreover, as Mr. Strauss himself pointed out, we have to think not merely in terms of plans, but also of design and construction, of civic design and of architecture, and finally of men.

In this concluding reference to the crucial importance of the architect, Mr. Strauss touched on a point which is the main theme of a further report of the Reconstruction Committee of the Royal Institute of British Architects, dealing with reconstruction and the architectural profession, and of a pamphlet, "Plan for Living", by Mr. Clough Williams-Ellis*. The report directs attention to the lack of use of the special knowledge of the architect in Great Britain during the War. The Select Committee on National Expenditure has several times pointed to waste of time and materials directly due to neglect of such knowledge and experience in furtherance of the war effort, but the present report from the Royal Institute of British Architects is concerned more particularly with the opportunities in the period of reconstruction after the War.

The failure of town and country planning to achieve the beneficial or significant results desired is attributed partly to neglect of the services of the creative architect, and the report emphasizes the desirability of establishing so far as possible the relations between architectural and planning functions before the end of the War, as well as examining the organization and potential capacity of the profession, and establishing publicly and in good time the extent of contribution it can make to national reconstruction. In regard to the design and external appearance of buildings, the value of a consultative panel of architects to whom reference should be obligatory is discussed in some detail. The importance of the status of the official architect is rightly stressed, whether in regard to Government departments or to local authorities, and in a section on the building industry after the War the functions of the architect and the importance of training are discussed with admirable lucidity and restraint.

Mr. Williams-Ellis contrives to discuss the position of the architect in post-war planning with equal felicity and detachment. His claim for the architect as the key man in the team is advanced with reason and an approach to objectivity. That it is the architect's job and not the engineer's, in the first instance, to replace our towns, is no unreasonable contention. The outlook of the modern architect is intrinsically the more likely to bring that touch of vision and creative insight essential to give us towns and countryside which hold the possibility of a full and happy life for all, and not merely a sanitary existence. It is the architect who has the vision and whose training in civic design includes the sociological, transport, engineering and legal questions that are subsidiary but essential elements in designing the successful and beautiful town.

The possibilities of securing the basic things required for a merely tolerable existence by reasonable forethought and planning to exclude inconvenience, ugliness, dirt, overcrowding, traffic delays, lack of sunlight or open-air amenities are ably discussed by Mr. Williams-Ellis. He reminds us of the opportunities which the bold and progressive ideas of to-day offer to constructive statesmanship, and of our comparative freedom from economic limitations if only we refuse to attempt to carry on with the old wasteful and inefficient muddle of unplanned living. If indeed we fail to seize the opportunities now before us, many of them presented by the removal of obstructions by bombing, and fail to develop a nobler community marked by the sanity, order and beauty which, as Mumford has reminded us, is the final test of an economic system, democracy will indeed have shown itself unable to learn from its present enemies.

---

* Plan for Living: the Architect's Part. By Clough Williams-Ellis. Pp. 36. Rebuilding Britain Series, No. 5. (London: Faber and Faber, Ltd.) 1s. net.

Fortunately technical ability and taste in architecture and town planning stand high in Great Britain to-day, and that ability and taste will have unprecedented opportunities. Both Sir Stafford Cripps and Mr. Lyttelton in their recent broadcasts, moreover, have indicated a new attitude in the Government which reflects the popular demand for something different and better. We are already entitled to assume that private ownership and vested interests will not be allowed to hold up or hinder changes needed in the public interest. Further, agreement has been reached on some such points as the optimum size for towns according to their location, siting and character, the sense of citizenship and civic pride and the provision of public amenities and cultural activities. True economy consists in efficiency, which includes not only right planning for traffic, public services, utilities, industries, commerce, health and education, but also for those no less vital needs known as amenities.

There is one point on which Mr. Williams-Ellis rightly insists. The success or failure of planning and reconstruction will finally depend on the character and ability of the men who do the job. Whether they are professional men such as architects or engineers, or administrative officials, or councillors, local or national Government servants, they must hold their posts in respect of ability, zeal and probity, and no other consideration whatsoever. On that condition the job is already half done. Without it, inefficiency, indifference and corruption will yet sabotage and bring to naught any programme or plan however brilliantly conceived.

The right note of moral conviction has been struck by Mr. Bevin, by Sir Stafford Cripps and by Mr. Lyttelton in their recent speeches. They go some way to remove the uneasiness suggested by Lord Portal's and by Mr. Strauss's speeches that progress has of late been retarded rather than accelerated. The urgent need remains for the Government to give the most explicit assurance of its earnestness and of its determination to produce the measures and policies in readiness for the testing time of armistice and the advance to a new peace economy. Nothing short of a Government declaration of its clear intention to retain control of industrial organization for so long as is necessary to bridge the hazardous period of transition, and simultaneously to secure the full adaptation of the production machine to the needs of reconstruction at home and overseas and the full employment of the working population for this purpose, will suffice to secure the maintenance of the national unity which is our safeguard from disaster. If the speeches to which we refer should check any undue pessimism, they should also stimulate unceasing pressure on the Government until there is forthcoming unmistakable evidence of the driving force and conviction of urgency which will ensure to the Minister of Works and Planning the powers and the legislation to enable him to formulate, and in due course to execute, a policy which will define and implement that outlined last February by Lord Reith and Mr. Greenwood and reiterated by Sir Kingsley Wood in his Budget speech. With nothing less will the country be content and without something more its war effort may well suffer. The Government should take the earliest opportunity of removing these doubts as to its continued determination to find "practical solutions for the immediate problems of a transition from war to peace", and to outline and amplify "a policy for the years following the War which will command the support of the nation as a whole and enable united action to proceed in peace as in war".

FALLACIES OF RACIALISM

Racialism against Civilization

By Dr. I. Zollschan. Pp. 64. (London: New Europe Publishing Co., Ltd., 1942.) 1s. 6d. net.

FOR many years Dr. Zollschan has been trying to rouse public opinion to a greater awareness of the ugly aspects of the racial theories concocted by Nazi propaganda, and its predecessors, to justify the aggressions by means of which a pathological group seeks to over-compensate for its deep sense of intellectual inferiority. The German disease is an old one, as the author shows. It was raging in Bismarck's time, and, whether voluntarily or not, Wagner increased the morbid tendency by his popularization of Teutonic heathendom in the "Ring of the Nibelungs". The Christian tradition was sick almost unto death in German universities; and theological writers, there as in Great Britain, were too often content to spin webs of sophistry to hide a void.

If we study human society objectively we cannot but realize that, whereas in the early and lowly stages of its evolution the individual is governed mainly by custom, the better equipped peoples show more tendency to value personality. Custom is apt to harden into a restrictive routine that sooner or later finds itself out of touch with ever-changing life, and the closed systems that have existed in the past have thus been led on through persecution of their best children to bankruptcy of ideas and collapse. This is the main argument for philosophic liberalism, which, in its turn, needs to guard against forgetfulness of the fact that man is a social being and has been such from the very outset of his story. To combine social order with the cherishing of personality as an agent of necessary adaptation is a chief task of mankind; and its difficulty is seen only too clearly when we realize that most 'blue prints' of a better world envisage a static condition, a sort of millennium that cannot exist. How to change without destruction of precious heritages and without degradation of personality is indeed the deepest of social problems. It is not to be solved by the selective analysis of purely intellectual effort; it must take into account the whole man and the whole social life of mankind.

Racialism supposes that mankind is divided into groups of long-distinct origin among which different heritages occur steadfastly. These heritages are supposed to be of different values in different cases; and those who claim that a certain heritage, for example, what is sometimes called the Aryan, or what is sometimes called the Nordic, is of outstanding value and endangered by intermixture, can only too easily work up an argument for domination and for elimination of others by the massacres and tortures in which the Nazis find delight.

Huxley, half a century ago, aptly said one should not speak of an 'Aryan race', any more than of a 'brachycephalic grammar'. Aryan languages spread in Europe and parts of Asia long ago; and no doubt considerable movements of population were involved, notably, it would seem, an exodus from the semi-arid grasslands of western Asia and southern Russia. But the vast majority of those who speak Aryan languages probably have only a little of the varied bodily heritages, if any at all, from those emigrants, in their make-up; and they are enormously varied in their physical, and, be it added, social and intellectual characteristics. The claim that the blond, tall longheads of northern Europe are in some special sense the descendants of these ancient emigrants is very ill-founded. The parallel claim that an ancient Nordic civilization arose autonomously and gave its achievements to Europe is too absurd to be discussed by anyone who has thought of the early history of the western Baltic with its fusion of at least two diverse immigrant cultures and, as usual, an interesting development following that interpenetration of different heritages and the accompanying liberation from the repressions of imposed routine obedience. It is exchanges that fertilize civilization.

There is little enough ground for ascribing a separate and isolated origin and development to the tall, long-headed blonds of northern Europe. Sweden still has individuals carrying characters, including a relative brunetness, that are widely thought to have been maintained from very early, probably Palæolithic times and are old-established even in Sweden. Archæology tells us of a number of immigrations, along the Arctic zone, from the south-east and from the south-west. Biology suggests that in this cool environment maturity comes relatively slowly and bony growth may be prolonged. The coincidences between the distribution of blondness and the area of marked cloudiness in this zone of low insolation are at least suggestive. It is thus highly probable that the different physical characters we possess have different histories and, however durable some bony features may be, they are not unchangeable. How much more is that the case with social and intellectual features!

Nevertheless, we must remember that there are interesting cases of inheritance of mental characteristics, of all grades, that are not to be ascribed by any means solely to environmental influences.

It may be that those who have lived for generations under a climate that almost forces people to activity to keep warm, and is nevertheless not so cold as to be severely repressive, may be energetic folk, may, in the terms of Sir Patrick Geddes, have a high ratio of katabolism to anabolism; but their energy may find outlets in constructive work just as well as in destruction. They are not committed to predatory effort by their biological constitution. Indeed, many a peaceful and constructive Dane very likely has more of this activity in him than the would-be Nordic Prussian who gratifies his *parvenu* Nordism and expends his intellectual activity on brutality to Poles, Czechs, Jews, French, Dutch, yea, even Norwegians and Danes.

Julian Huxley contributes a characteristically vigorous and thoughtful preface emphasizing man's power of conceptual thought which can build up a tradition; in other words, can add a transmissible heritage that need not be linked to a physical one. As he says, "most of the achievements on which our 'white' or 'Nordic' civilization is based we owe to the brains of brownish Asiatics—the alphabet, agriculture, building in stone, metallurgy, the wheel and so forth". He, like Dr. Zollschan, makes his point clearly that one of the novelties introduced by man into evolution was that of universal and conscious values which, once discovered, have an almost independent existence, a momentum of their own.

The preface might have added a little more spice had its author recalled the famous verse of Hilaire Belloc which describes the Nordic man: "His legs are long, his wits are slow". Whether Belloc's generalization has more scientific value than that of Houston Stuart Chamberlain and the Nazi demagogues one would not like to have to decide; but it at least has a touch of humour about it and none of Hitler's mentors—Haushofer, Streicher, Rosenberg—could ever be credited with that.

The presumptuous claim that racialism is founded on Darwin's work might be more drastically destroyed than it is in Dr. Zollschan's book. He is clear, as every thinker must be, that neither can victory in war be a criterion of survival, nor can survival as a biological fact be confounded with superiority of value. What he might have emphasized is that the idea of the Darwinian process as mere struggle is inadequate. The mammals have become a large, powerful and widespread group largely thanks to the elaboration among them of maternal devotion; and that factor has been much developed in the species of mammal to which we belong, one of the most widely distributed of all. With this development among mammals has gone an elaboration of group life, which, again, has had a unique blossoming in our own species. We are still, of course, at an early stage of our social evolution, and have a great deal to learn.

Dr. Zollschan sees what a large part religion plays in social maintenance and evolution. He sees, too, that insistence on untenable, anthropomorphic religious ideas has weakened the social influence of traditional religion among us. The Nazi racialism and other varieties of totalitarianism are in a large measure attempts to find a new religion which, as the author well says, in these days must inevitably try to achieve a link with the revelation of science. Whatever may be thought concerning other forms of totalitarianism, the Nazi variety essentially exemplifies the revolt of the sub-human and the degenerate against the advance of the social and ethical towards a more complete humanism.

The battle against Nazi decadence is the battle for peace and goodwill and their outcome in the wide humanism that science is making possible.

H. J. FLEURE.

EMBRYOLOGY OF THE RHESUS MONKEY

Embryology of the Rhesus Monkey (*Macaca mulatta*)
Collected Papers from the Contributions to Embryology, published by the Carnegie Institution of Washington. (Publication No. 538.) Pp. iii+148+52 plates. (Washington, D.C.: Carnegie Institution, 1941.) 1 dollar.

IN 1925 the Carnegie Institution of Washington undertook a programme of research into the problem of reproduction in monkeys. Its first step was to establish a colony of rhesus macaques in its Department of Embryology, which was then directed by Dr. George L. Streeter. The Department is next door to the Anatomy School of Johns Hopkins University, where a few years earlier Dr. George W. Corner had begun similar work on the same species of primate. The close affiliation of the two laboratories proved fortunate, and the success of the Institution's programme of research, now directed by Dr. Corner, is marked by a number of monographs published in its "Contributions to Embryology". Five of these monographs have now been collected in a single volume.

The volume opens with Hartman and Corner's paper on the first maturation division of the macaque ovum. Like the others of the series it is beautifully illustrated; and it demonstrates that, as in the vast majority of mammals, the first maturation division occurs within the Graafian follicle just preceding its rupture. The second paper, by Lewis and Hartman, takes the story a stage further and discusses fertilized and unfertilized ova recovered from the Fallopian tubes, and the further behaviour of which has been studied *in vitro*. The process of segmentation has been successfully filmed, but attempts to fertilize the eggs *in vitro*, unlike similar experiments with rabbit eggs, failed. The third monograph, by Heuser and Streeter, deals with the early development of the embryo. Cleavage of the fertilized ovum leads to a selective distribution of the complex material of the original one-cell egg into the daughter cells of, first, the morula, and then the blastocyst. This process represents the specialization of 'primary orders of tissue', a process which the authors point out depends on intrinsic genetic rather than environmental factors, and by which the auxiliary elements of the egg separate themselves from the true formative elements. Strictly speaking, it is a process which does not represent growth, since the mass of the cells of the free blastocyst is in fact less than that of the original egg cell. The moment this primary differentiation has occurred, its cellular products themselves begin to exert a mutual influence upon each others' further development.

The factors responsible for the transport of the blastocyst and the determination of its site of implantation, which occurs about the ninth day after ovulation, are unknown, but the process of implantation itself has been studied in the greatest detail. So, too, has the differentiation of the 'germ disc', which in its early stages is synonymous with the so-called 'embryonic ectoderm', and which the authors regard as exercising a function similar to that of the dorsal lip of the blastopore, in so far as the disc has a "dominating influence in determining the fate of the neighbouring auxiliary cells as well as those migrating out from the germ disc itself". During this early stage of development the disc is growing as a tissue culture in a fluid medium provided by the surrounding auxiliary cells. It owes its organizing propensity to the fact that its constituent cells represent an unspecialized residuum of the original germ plasm. Further segregation of cells, as development of the disc proceeds, brings these particular cells into relation with the primitive streak. It is not until the latter has given off definitive embryonic ectoderm, mesoblast and gut endoderm cells that the residuum of primordial germ plasm is finally used up. The endodermal contribution of the germ disc is not clearly distinguishable from the cellular proliferation, perhaps induced by the germ disc, of the primitive endoderm cells—which are a direct product of the primary segregation and cleavage of the egg.

Heuser and Streeter thus define a first order of segregation or specialization in embryonic development in which the formative elements of the fertilized egg become separated from the auxiliary elements; a second order of segregation in which the formative elements containing the residuum of primordial germ plasm become organized as the primitive streak, which is the locus of the "second order of specialization"; and further orders of segregation, for example, the separation of the ganglion crest from the neural ectoderm, which finally become too numerous to be kept in serial levels. The general conclusions reached are of considerable importance to comparative embryology. The authors do not subscribe to any simple and far-reaching phylogenetic theory. As they put it, "the embryo at all stages is a living organism and is to be analysed as a biologic problem rather than purely a morphologic abstraction". For example, "what were thought to be vestiges of great phylogenetic importance appear, in many instances, to be temporary embryonic structures, essential to a particular period of development."

The fourth monograph of the series is by Schultz, and discusses fœtal growth, with special reference to body proportions, certain ectodermal structures and ossification. The rhesus monkey at birth is relatively much more advanced than a new-born human infant, but fœtal growth-changes in body proportions are much the same in both species. A notable exception is the brain, which in the new-born rhesus monkey is about half the final size achieved in post-natal life, and in man a quarter. The fifth and final monograph of the volume, by Wislocki and Streeter, is a very detailed discussion of placentation. It demonstrates clearly that, in the differentiation of the trophoblast, there is a striking similarity between man, anthropoid apes and the rhesus monkey. The human placenta can be regarded as having been derived from the catarrhine variety by the acquisition of an interstitial mode of implantation. Here the authors depart from a widely accepted view, in so far as they suggest that human interstitial implantation is not due to the trophoblast becoming more "invasive", but to the endometrium becoming less resistant to invasion—as shown by the absence in man of proliferation of the uterine epithelium at the site of implantation. This paper ends with a stimulating discussion of the functional relationships between egg and endometrium.

The Carnegie Institution is both to be congratulated on the achievement which the volume represents, and to be thanked for having made these five monographs available between the same covers. It is to be hoped that this is only the first of a series of similar ventures, and that other volumes will follow in which further related studies of primate reproduction and growth will be made available, in the same convenient form, to students of the subject. S. ZUCKERMAN.

Handbook of Chemical Microscopy

By Prof. Émile Monnin Chamot and Prof. Clyde Walter Mason. Vol. 2: Chemical Methods and Inorganic Qualitative Analysis. Second edition. Pp. xi+438. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1940.) 30*s.* net.

THE rapid development in recent years of microchemical methods of analysis has called forth an excellent series of text-books on various aspects of the subject and, of these, Chamot and Mason's "Handbook of Chemical Microscopy" holds a deservedly high place. In the second edition of vol. 2 now under review, most of the subject-matter in the original work (reviewed in NATURE, 130, 619; 1932) has been retained but a number of new tests have been included, some of them employing organic reagents such as dipicrylamine, nitrobarbituric acid and diphenylcarbazide. The most extensive additions have been to the sections dealing with the detection of the alkali metals, the metals of Group IV of the periodic classification and the anions of the sulphur group where tests have now been included for the polythionates; a scheme for the identification of the various sulphur-containing anions has also been drawn up. To illustrate these new procedures there have been included forty-eight additional photomicrographs. All the photographs are excellently clear and the same care has been expended in making the descriptive matter lucid and yet concise. The text is remarkably free from errors, while there is a good index. The volume is handsomely bound, so that the authors and publishers have collaborated to produce a book which is indeed a joy to handle and to use.

Beyond the "Isms"

By Olaf Stapledon. (Searchlight Books, No. 16.) Pp. 128. (London: Martin Secker and Warburg, Ltd., 1942.) 2*s.* net.

THERE has been a remarkable spate of books inspired by the War, and they are none of them of the furious anti-Hitler type which the case would warrant. The writers are stirred by social passion among themselves. Let them use the war as binding the nation in determined and religious ardour which will stretch far beyond the war itself. Sir Richard Gregory's "Religion, Science and Civilization" is, of course, of ampler scope and full of interesting matter. It leans in the same direction as Mr. Stapledon in stressing the religious side but avoiding any orthodox religions. The most striking feature of all these religious-social war exhortations is that they come from and go to the religious who frankly discard the accepted creed of the Church of England or any other church. Their attitude is forward-looking, but not attached to any church. The future of organized religion will therefore become more and more vague and insincere, unless the discard of impossible doctrines and legends is frankly made.

This is being done in certain churches, and, of course, in multitudes of private prayers.

The crisis is a useful one. A new archbishop to set the tone.

Religion is our attitude towards the Infinite in company with and for the good of others. This must differ from worshipper to worshipper. The Infinite may find its own. F. S. MARVIN.

Supplement to the British Pharmaceutical Codex, 1934

Part 1: Monographs (New Monographs). Pp. iv+101. (London: The Pharmaceutical Press, 1942.) 5*s.* 6*d.*

THE British Pharmaceutical Codex was last published in 1934, but it has been brought up to date by the issue of three supplements in the last few months. The first supplement deals with dressings, while the second contains additions and amendments to the formulæ for galenical and other preparations in Part 3 of the Codex. It is designed to overcome difficulties arising from the War by authorizing the use of alternative formulæ for preparations in which certain of the ingredients are either in short supply or reserved for more important purposes. The third supplement, which corresponds with Part 1 of the Codex, is most likely to interest the scientific man. It contains 66 new monographs describing substances recently introduced in medicine, and substances liberated by the recent emergency legislation from the restrictions imposed by foreign patents. About half of these substances have already been described in the various addenda to the British Pharmacopœia; the remainder now receive their first official description in Great Britain. The sections on "Action and Uses" in this supplement will interest many who are not concerned with pharmaceutical details. They give a summary of some of the more important recent advances in pharmacology and therapeutics, and are more balanced and more authoritative than many of the corresponding sections in the Codex, which have retained much that is now archaic, probably because there was no definite reason for believing it to be incorrect.

Aircraft Instruments

By George Ellis Irvin. Pp. x+506. (New York and London: McGraw-Hill Book Co., Inc., 1941.) 35*s.*

THIS book is composed mainly of detailed descriptions, with comprehensive maintenance and testing schedules, of standard American products; the thoroughness which is characteristic of American trade booklets is evident in the treatment. Other than the omission of oxygen instruments and of the absence of synchroscopes from the chapter "Tachometers and Synchronizers", the volume covers most of the American instruments in general use. It is excellently illustrated and reproduced, and in this respect is marred only by a number of proof-reading errors.

The author makes little attempt to explain the physical conceptions leading to the design of flight and navigation instruments, and it is perhaps as well that the scope of the book is restricted in this direction. For example, the statement "Air-speed indicators show the speed of the airplane relative to the air through which it is travelling" is incorrect, unfortunately for the navigator; and in the chapter on compasses, some confusion over the north end of a magnet is evident.

The useful properties of all the instruments are fully described, but their limitations, both fundamental and in practical usage, receive little critical attention. The book is useful for reference purposes, but it cannot be recommended to the serious student of aeronautics or instrument design.

THE WEED PROBLEM*

By PROF. E. J. SALISBURY, C.B.E., F.R.S.

TO define a weed is not an easy matter since this term of opprobrium is applied in different ways by different persons. Probably the best definition is that of a plant growing where we do not want it. Nevertheless to many the designation implies a certain measure of uncontrollability, and it is more particularly these weeds, which are the bane of the farmer and the gardener, that concern us here.

It has been estimated that, before the War, the cost of weeds to Great Britain was of the order of some sixteen and a half million pounds a year. It is, indeed, probable that this is a very conservative estimate, since the monetary losses due to the indirect effects of weeds, which are by no means inconsiderable, are well-nigh impossible to assess.

The most evident effect of weeds is that they compete, with our crop and garden plants, for such essenials as water, the mineral nutrients necessary for all types of vegetation in smaller or larger degree, the carbon dioxide of the air, and for the radiant energy upon which the manufacture of sugars by the green leaf depends.

The competition for the soil moisture is of a dual character. If plants are growing in a very wet soil the amount of water which the plant can take up, provided there is adequate aeration, is probably determined more by the efficiency of the internal water-conducting system than by the extent of its roots. But when the moisture in the soil is low in amount the extent of the absorbing surface of the root which is in contact with the soil is often the governing factor in the supply, and it is naturally under just these conditions that the water supply is most important. The extent of the root system is also of importance as affecting the amount of nutrients available to the plant, since upon this will depend the volume of soil exploited. This is especially true with respect to those nutrients in regard to which the soil is most deficient.

The development of the root system of a plant is now known to be greatly influenced not only by the aeration and texture of the soil but also by the presence of root systems. The mechanism of this interference is not yet fully understood. It is likely that the intake of oxygen and the release of carbon dioxide during the respiration of roots may play an appreciable part. Indeed, most roots are intolerant of high concentrations of carbon dioxide in the soil atmosphere. The presence of numerous weed roots will therefore compete for the available oxygen and render the soil atmosphere less favourable for root development and the intake of nutrients. In addition there is experimental evidence that soluble substances are produced by roots, perhaps during the breakdown of dead cells, which are of a toxic nature and vary in their deleterious character according to the species concerned.

Some astonishing figures have been obtained by the Canadian botanist Pavlychenko showing the extent of the root system of cereals when grown with and without the competition of other plants. When wheat and rye were raised as single individuals with no other vegetation in their neighbourhood and measured as if all the roots were cut off and placed end to end, as one continuous thread, the total length was more than forty-four miles for a wheat plant and more than fifty miles for one of rye. When grown in drills, as in normal cultivation, so that the crop plants in the same row compete with one another, the root-lengths diminished to from one half to two thirds of a mile, while when weeds were present in addition, between the rows of cereals, the total length was only about one ninth of a mile. The presence of charlock in a field of wheat can reduce the root system of the cereal to one fifth or even a tenth of its extent when weeds are absent.

There is reason to believe that root competition and the resulting effects upon the supply of nutrients may often be the most important of the deleterious effects brought about by weeds. Weeds thus deprive our crop and garden plants of water and nutrients in two ways. First by reducing the volume of soil occupied, and secondly by depleting those essential requirements which the diminished volume of soil contains.

Sometimes the chief nutrient thus depleted is nitrogenous material, and the harmful influence of some weeds can be greatly alleviated by applications of nitrogenous fertilizers. Even where there is no root-competition, mere crowding, as Dr. Brenchley showed with plants in separate containers in water culture, in itself increases this nitrogen requirement. But it must be emphasized that the nearer any nutrient is to the minimum requisite for crop growth, the more likely it is that the presence of weeds will bring about a real deficiency.

We know that weeds absorb the essential elements in very different amounts. Thus the common bracken contains an exceptionally high proportion of potash, so that plants in competition with bracken are liable to suffer from potash starvation, but for the same reason bracken fronds, cut early in the season, provide a most useful material for composting in these days of shortage in potash supplies.

We now know that broad beans and beets, in particular, require minute traces of boron, and possibly all plants require some. Lack of minute quantities of copper and cobalt in a soil, and hence in the herbage developing upon it, may lead to serious and even fatal diseases in sheep. The study of these micronutrients is as yet in its infancy, and one of the gaps in our knowledge that requires filling is in respect to the effect of weeds in influencing the availability of these essentials for healthy growth. We do know, however, that these micronutrients are often present in amounts only just adequate for the crop, and one or other is not infrequently deficient, at least in an available form.

Some weeds take up these rarer elements in quantities as great or even greater than do our garden and crop plants. It is therefore extremely likely that the presence of weeds competing for these micronutrients may accentuate even if they do not create deficiencies.

So far as I am aware, gold has not yet been shown to be essential for vigorous plant growth, but data obtained by the distinguished Czechoslovakian plant physiologist, Prof. B. Němec, showed that whereas a metric ton of dried maize contained only 2 gm. of gold, that objectionable weed the field horsetail (*Equisetum arvense*) contained 63 gm. and the marsh horsetail (*E. palustre*) 610 gm., although the same dry weight of the soil only contained a tenth of a gram. Let me hasten to add that the yield per acre is not sufficient to warrant the cultivation of horsetails for this purpose.

---

* Substance of a lecture delivered at the Royal Institution on April 30.

There is another aspect of the weed in relation to the rarer elements that is of considerable economic importance in certain districts. Some trace elements, far from being beneficial to stock which feeds upon the herbage containing them, are extremely poisonous. A particularly striking example is afforded by the seliniferous soils of the United States. The pastures which grow on these soils may be quite innocuous, since the comparatively insoluble selenium is only absorbed in small amounts by the grasses and many species of herbs. But certain weeds which occur in these pastures, particularly species of milk vetch (Astragalus spp.) have such a capacity for absorbing and accumulating selenium that they render the herbage highly poisonous to browsing animals. The so-called 'teart' pastures of Somerset, Gloucester and Warwickshire are now known to be deleterious to cattle owing to the presence of molybdenum in the herbage, but whereas dried rye-grass growing on these soils will contain only about one part of molybdenum in a thousand, white clover will contain about nine and a half times as much. Hence on these soils the clovers, which are desirable constituents of herbage in most areas, must be classed as weeds. Applications of ammonium sulphate to such pastures reduce their toxicity partly because there is an increased proportion of grass in the herbage but also because under the more acid conditions thus induced the uptake of the molybdenum is diminished.

These few examples suffice to show that the relation of weeds to the rarer elements is an important one concerning which far more information than at present available is desirable. The amounts involved are extremely small. It has, for example, been estimated that the requisite cobalt for healthy growth of sheep in New Zealand is of the order of one part in twenty million.

Competition for light by weeds and cultivated plants is often pronounced in the seedling stages, when weeds may form a canopy of foliage that precludes all but a small fraction of the radiant energy, necessary for green leaves to manufacture the plant's food, from reaching the seedlings of our crop or garden plants. But such competition for light is by no means confined to the juvenile phases of development or to recently disturbed soil. The plantains and daisies on our lawns and golf-greens suppress the grass mainly because their close-pressed rosettes cut off the light from the turf beneath. But no better example of competition for light could perhaps be found than is exhibited by that weed of the hedgerow, the common elder (*Sambucus nigra*) because it illustrates in a striking manner those biological features which most commonly render species especially aggressive in this respect. The first of these is the remarkable capacity of this shrub to form robust shoots of great length in a single season. These may attain more than six feet and quickly outstrip the shoots of their neighbours. Secondly, the very early development of the new foliage, which expands before that of other deciduous hedgerow shrubs, confers a by no means unimportant advantage in time. Thus in the south of England the average date for the beginning of leaf expansion of the elder in a normal season is about the middle of February, whereas for our commonest hedgerow shrubs, the hawthorn, blackthorn and hazel, the average date is about the third or fourth week in March. Lastly the leaves of the elder are large and collectively constitute a canopy of foliage that is relatively impermeable to the light. The total effect of these features is that the elder can create an efficient sunshade above the surrounding hedge before the leaves of the other shrubs are even fully expanded. Added to which the seedlings of the elder are remarkably tolerant of deep shade, so that they can develop under conditions that might suppress other species, and are not infrequently to be found within the hedge itself.

In addition to the direct effects of weeds in depriving cultivated plants of light, water, and nutrients, there are other important indirect outcomes of their presence, particularly as host plants of pests which enable the parasites and predators to persist in an area from which the appropriate cultivated host is temporarily absent. Thus the flea beetle, which in the past season was such a devastating pest on turnips in some areas, finds an alternative host on the charlock. Weeds also harbour eelworms and virus diseases, while the slime fungus which causes club-root disease of our cabbages and other species of Brassica, is often to be found flourishing on Cruciferous weeds, particularly treacle-mustard (*Sisymbrium officinale*).

With respect to insect pests that attack both crop-plants and weeds, our knowledge of deterrents and attractants, though at present meagre, offers the interesting possibility of treatment that shall not merely render the cultivated plants relatively immune but may also induce such insects to afford biological control of the weeds themselves.

The solution of the weed problem can only be found by concerted action directed on one hand towards weed destruction and on the other against their reappearance. Methods of destruction, especially by chemical means, are often immediately successful and even spectacular in their achievements, but they represent an expenditure of money, material and human effort that might in many instances be avoided. Preventive measures are usually far from being spectacular and indeed are apt not to be accorded the recognition they deserve.

Cultivation of the soil by hand, while affording an effective means of control of annual species and some perennials, is dependent upon an adequate supply of inexpensive manual labour. On the farm, mechanical cultivation can achieve much to mitigate the labour difficulty, but it should be remembered that the effective application of mechanical methods to the fallow and the growing crop demands forethought in the lay-out and spacing of the plants to this end. The chief drawback to cultivation as a means of weed control is that the repeated disturbance of the soil that may be required to keep the land clean is liable to do as much harm by disturbance of the roots of the cultivated plants as it does good by the destruction of the weeds.

The high cost of labour and the risk of undue root disturbance have been responsible for the development of chemical means of control by spraying. Of these the most effective so far devised is the method of spraying with a dilute solution of sulphuric acid which was utilized with very satisfactory results in the United States and France and has been successfully developed by Mr. G. E. Blackman in Great Britain for the control of weeds in onions and other crops. By the application of a suitable amount of lime the effects of the acid on the soil are neutralized. Nitric acid has also been employed and has the merit that it increases the nitrogen content of the soil which weeds are so liable to deplete. Some measure of control has been achieved by the use of fertilizers such as ammonium sulphate and cyanamide, and if such methods could be rendered more effective they clearly offer the advantage of avoiding expenditure of chemicals that are not in themselves of value to the crop. If more effective control by means of fertilizing sprays or dusts could be attained it would probably be greatly to the advantage of agriculture and horticulture in more ways than one. Only time can reveal the long-term influence of chemical methods on soil-structure and fertility.

Even with the most effective chemical sprays destruction of weeds is rarely complete, and those that remain, because they are freed from the competition of their neighbours, may attain a large size and in considerable measure compensate in seed yield for the small number of individuals that ripen fruit. For this reason the supplementing of mechanical or chemical control methods by hand labour may well be profitable.

On unplanted soil, drastic methods such as the application of sodium chlorate are sometimes effective against deep-rooted perennials, but little is known as to the residual effects upon the soil structure and the microscopic forms of life.

Many perennial weeds, such as the creeping thistle, the bindweed and the hoary cress, can produce shoots from quite small fragments of the roots even if these be comparatively deeply placed in the soil. Repeated destruction of the overground shoots of these until the underground parts are exhausted of their reserves of food, offer the best hope of their eradication. This has proved effective with the bracken, although the cutting has to be carried out two or three times at intervals of five or six weeks over a period of from three to five years. It has been aptly said that to stop cutting bracken before eradication is complete is like leaving a smouldering fire untended.

Biological control by the encouragement of parasites, either insect or fungal, has been utilized with varying degrees of success. Insect control has proved valuable against the cactus pest of Australia (see NATURE of September 13, 1941, p. 303). The control of bracken by means of a fungus has been attempted in Great Britain. The great difficulty in the development of biological methods is to find a parasite which is strictly limited to the kind of plant we desire to control and which will not sooner or later itself become a pest on some related or even unrelated species which we cultivate.

The weed problem is apprehended as in reality a dual one: the first being the problem of eradication, and the second the problem of preventing reinfection. The former is often far more readily accomplished than the latter, which can in general only be partially achieved.

The second category, preventive measures, are not only perhaps the most important but also their application leads us to study the biology of the weed species and thus to discover their most vulnerable points of attack.

However effectively we may have destroyed existing weeds, it is clearly imperative that they should not be re-introduced by the sowing of impurities with our seeds. Modern screening methods which take advantage of many of the differences between crop seeds and those of other plants such as size, weight, and surface texture have accomplished much, and the number of weeds that we inadvertently sow to-day are few compared with half a century ago. The former prevalence of darnel grass (*Lolium temulentum*), which was evidently a pest in Shakespeare's day, of the blue pimpernel (*Anagallis coerulea*), and the pheasant's eye (*Adonis autumnalis*), which are to-day rare cornfield weeds, was due to their repeated introduction in seed imported from the south of Europe. Even now vast quantities of weed seeds are annually sown with grass and clover seed all over Great Britain.

The returns of the official seed-testing station show that perennial rye-grass seed commonly contains 2–4 per cent by weight of impurities, cocksfoot seed about 9 per cent, and meadow foxtail between 30 per cent and 40 per cent. Clover seeds, too, often contain between 4 per cent and 9 per cent. To understand what such proportions of impurities mean in terms of actual weed seeds, I have calculated that in every year, with the sowing of clover and grass, more than six billion weed seeds were probably also sown throughout Great Britain.

Even could we completely clean the soil of growing weeds and ensure that no weed seeds were afterwards sown, we should probably not be free from weeds for a number of years owing to the long period over which buried weed seeds can remain alive.

Careful experiments carried out on seeds buried in the soil and then placed under conditions favourable to germination, after the lapse of increasing periods of years, have shown that the seeds of the shepherd's purse (Capsella) and fat hen (*Chenopodium album*) can retain their viability for at least thirty-five years, and those of the crisped dock (*Rumex crispus*) for at least sixty years. Others, such as those of the blue pimpernel, retain their viability for even longer periods.

Apart from viable seeds already in the soil and possible impurities in the seeds that we sow, there is another source of infection that is by no means negligible, namely, the accidental introduction in manure, on our boots and clothes, and even on the implements of agriculture. The moist heat that is generated as manure ferments, or in the compost heap, does, it is true, destroy the viability of many of the contained seeds, but many there are which can not only pass through the alimentary canal of the cow or horse with unimpaired or even enhanced germination, but also can survive the subsequent fermentation.

It is worth while dwelling somewhat on the accidental carriage and distribution of seeds by our own activities, since all too little attention has been paid to this by no means infrequent occurrence.

Some years ago I carried out a number of experiments designed to test the extent to which seeds were carried about in the mud upon our boots. Mud brought into churches which had paved paths leading to the porches was placed on sterilized soil and moistened. The seedlings which afterwards emerged were found to be mostly grasses, but various other weeds were also present. It is reasonable to assume that these seeds might have been carried appreciable distances before the mud dried sufficiently to fall off. Even more effective carriage in mud is accomplished in the patterned tread of motor-tyres and the wheels of farm carts and lorries, as well as those of private cars, and are an effective means of dissemination over long distances. There is little doubt that the wayside pineapple weed (*Matricaria suaveolens*), which originated from Oregon, owed its rapid spread throughout Great Britain to this means of dispersal.

Our clothes, too, are a frequent means of seed carriage, and if after a country walk one turns down the 'cuffs' of one's trousers it is amazing the collection of seeds that can be obtained. I have sowed a number of such collections after walks in diverse types of habitat. In one instance there were no less than 325 seedlings produced when the trouser brushings were sown on sterilized soil. Of this total 284 were seedlings of various grasses, while the remaining 41 comprised five different kinds of weeds.

It is important to recognize that vegetative propagation by means of shoots that arise from the roots, though an unusual feature, is characteristic of several of our most pernicious weeds such as the creeping sorrel (*Rumex acetosella*), the creeping thistle (*Cirsium arvense*, the field convolvulus (*Convolvulus arvensis*), and the yellow toadflax (*Linaria repens*). The importance of such vegetative methods is that whereas the seedling can only successfully develop in a relatively open spot where the small food reserve in the seed will enable it to grow into the light, the shoot from a root or from an underground stem has the much larger reserves of the adult parent to draw upon and so is able to extend unchecked by the shade of its neighbours.

Owing to the prolific production of seeds (for example, a single fruit of groundsel has the potentiality of infesting about sixty-five acres in three years), it cannot be urged that because the number of seeds inadvertently introduced is small, it is therefore a matter of indifference. Indeed, when we weed our gardens it is well to remind ourselves that unless the ground is cleaned completely of all weeds our efforts may merely result in the survivors attaining to large dimensions, and thus in no small degree compensating by the magnitude of their yield for the dearth of individuals.

We must, moreover, recognize that our efforts to eliminate weeds will automatically tend to render our tasks more difficult unless it is complete. So, too, in the use of large-scale weed treatment in agriculture, it is important to bear in mind that a remedy that is only partial may in fact merely destroy the strains that are more easily killed and so we leave behind the more resistant types free from the competition of their less robust relatives; hence the latter state is worse than the first, for we have selected out a strain or strains that demand more drastic measures to compass their destruction.

If our attempt at suppression is at the seedling stage, we must know whether germination is commonly 'simultaneous' or normally 'intermittent' and what is the period of dormancy of buried seeds? So, too, it is essential to our success to know the potentialities for vegetative increase. Crops of weeds like those of economic species have their soil preferences and differential response to nutritional stimulus. In South Australia it was found that the application of copper salts to copper-deficient soils resulted in an increased yield of the cereal crop amounting to from three to eight times, but the effect upon the weeds was only to increase them by 50 per cent. It is, indeed, manifest that to combat effectively the avarice of weeds it is essential to have a far more intimate acquaintance with their biology, in all its aspects, than we at present possess. 'Know thy enemy' is as sound advice in horticultural and agricultural hygiene as in any other type of activity, and perchance we may find that a species that appears in the guise of an enemy may sometimes function as a friend.

X-RAY TECHNIQUE IN THE INDUSTRIAL LABORATORY*

By H. P. ROOKSBY
Research Laboratories of The General Electric Co., Ltd.

THERE are two main ways in which X-rays have become of immense practical importance in the industrial field. The great penetrating power has been utilized in the technique of radiography for the examination of what may be described as the macrostructure of solid bodies and objects. In X-ray crystal analysis the diffraction of X-rays by the regular pattern of atoms in a crystal has been utilized to elaborate and supplement chemical and other physical methods of examining the nature and properties of a material.

X-Ray Tubes

The basic design of the modern X-ray tube is that of an evacuated jar or envelope containing two electrodes between which a high potential is applied. In an electron tube for radiographic work, the target or positive electrode usually consists of a hollow water-cooled block of copper into the face of which is set a small disk of tungsten. The other electrode is a hot tungsten filament surrounded by a metal cap or hood, the arrangement being to focus the electron stream from the filament on to the target face in the form of a rectangle. When viewed at an incident angle of about 20°, the rectangular source of the primary X-ray beam is foreshortened to a square. Comparatively compact X-ray tubes encased in oil and with shock-proof high-tension cabling are available for operation at 200 or even 400 kilovolts. Demands for radiation of great penetrating power have led to the building of units to operate at one million volts and more. One of the most recent which may be used at a million volts utilizes Freon under pressure as the insulating medium and a resonance transformer as high-tension generator. The length is only 7 ft., the X-ray tube and generator being enclosed in the one envelope[1].

For crystal analysis it is not necessary to operate the X-ray tube at voltages above 60–70 kilovolts. Moreover, some means has to be found for simple alteration of the nature of the source of X-rays in order that several different wave-lengths are available. The requirements are best met by the continuously evacuated demountable X-ray tube, with interchangeable targets each faced with a different metal. The rectangular focus is frequently viewed at almost glancing angle so that a source of X-rays effectively approaching a short line is obtained.

The radiation from an X-ray tube consists, in general, of two parts, the 'white' or continuous spectrum radiation and a line radiation the wavelengths of which are characteristic of the radiating element. It is the continuous radiation which is of practical value in radiography; in the continuous spectrum there is a sharp lower limit of wave-length depending only upon the applied voltage and decreasing with increase in voltage. To a great extent the penetrating power of a heterogeneous X-ray beam increases as the lower limit of wave-length becomes shorter, so that penetrating power may be largely controlled by the X-ray tube voltage. It must be chosen to suit the subject of examination if maximum clarity and contrast on the X-ray negative is to be obtained. As a general rule, the X-ray tube voltage should be adjusted to the lowest value at which reasonable penetration of the object is obtained. The distribution of wave-lengths or 'colour' of the X-ray beam may also be modified by inserting appropriate metal filters in its path. There is then a suppression of the longer wave-length components. By such means, and by the employment of lead intensifying screens consisting of very thin sheets of lead placed on either side of the X-ray film, scattering and secondary radiation from the specimen are substantially reduced[2]. At the higher voltages this results in a considerable improvement in clarity and definition of the image.

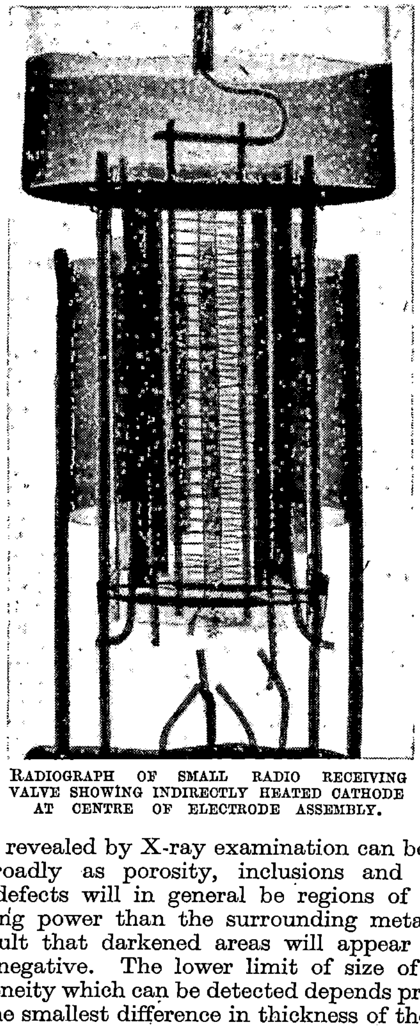
* Abridgement of three Cantor Lectures delivered before the Royal Society of Arts on March 16, 23 and 30.

Radiography

Probably the most important sphere of application of radiography in the industrial field is the examination of metal castings. The defects in castings that may be revealed by X-ray examination can be classified broadly as porosity, inclusions and cracks. These defects will in general be regions of smaller absorbing power than the surrounding metal, with the result that darkened areas will appear on the X-ray negative. The lower limit of size of an inhomogeneity which can be detected depends primarily upon the smallest difference in thickness of the metal that can be registered on the negative. For steel of the order of 2 in. thick a change of about 1 per cent may be detected. With castings of the light aluminium and magnesium alloys, which are of such immense importance in the aircraft industry, the sensitivity is generally lower, for, while it is easy to obtain adequate penetration it is more difficult to obtain good contrast.



RADIOGRAPH OF SMALL RADIO RECEIVING VALVE SHOWING INDIRECTLY HEATED CATHODE AT CENTRE OF ELECTRODE ASSEMBLY.

Radiography has not perhaps been so extensively applied to the examination of assemblies, but in many varieties of radio valve radiographic inspection has proved of great aid to development and manufacture. One of the original studies was of the large water- and air-cooled transmitting valves. Sufficient penetration of the opaque copper anode had to be obtained to delineate sharply the tungsten and molybdenum inner electrodes, and yet leave a clearly defined outline of the anode to give information as to the concentricity of the whole assembly. The technique has been extended to many special forms of small thermionic valve with opaque envelopes in which clearances between the various components are particularly critical. Distortion and deformation of the parts of the assembly during operation and during life can also be studied by taking a series of X-ray photographs at different stages, and such a series may often prove a useful guide to improvements in design because the points at which imperfections in construction occur can be so readily observed. Even when the envelope of the valve is of glass, the only practical way to examine a component at the centre of the electrode system (a tungsten heater inside a thermionic cathode for example) is by X-rays.

X-Ray Crystal Analysis

With the verification of the suggestion by Laue that the X-ray wave-lengths should be of the right order for diffraction by the interatomic distances in crystals, there commenced an extensive study of the structure of crystals. The basis of practically all X-ray diffraction measurements is the law first formulated by the Braggs, namely, $n\lambda = 2d \sin \theta$; the X-rays are regarded as being reflected from planes of atoms spaced apart by a distance d.

Of the various methods devised for the determination of crystal structures, one is of outstanding value for use in the industrial laboratory. This is that commonly known as the powdered crystal method, and consists essentially of examining photographically the diffraction effects obtained when a finely powdered crystalline substance is irradiated with a pencil of monochromatic X-rays. A single wave-length incident upon a crystalline powder gives rise to a number of cones of diffraction corresponding to the atomic planar distances of which the characteristic crystal structure is made up. The cones of diffraction may be intercepted by a photographic film in several ways. In the simplest technique a flat film placed behind the specimen perpendicular to the direction of the X-ray beam records a series of concentric rings. Alternatively, the film may be placed so that the primary X-ray beam has to pass through the film before striking the specimen, the back-reflexion method. Of widest application perhaps is the cylindrical powder camera, in which narrow strips of film on its periphery almost surround the specimen which is mounted on its axis. The X-ray pattern consists then of slightly curved lines, is unique to each crystalline element or compound, and hence may be employed as a crystal 'fingerprint' for identification purposes.

Very careful design of cylindrical powder cameras is required in order that patterns of high definition and clarity should be obtained. For example, it is essential to ensure that after collimation the primary X-ray beam travels through the camera without impinging upon any other part. Usually knife edges are arranged to record fiducial shadows on the film at a diffraction angle of approximately 85°. This enables accurate measurements of interplanar spacings to be made and errors due to film shrinkage, mounting of specimen, etc., to be avoided[3,4]. The powder is attached with an adhesive medium to a fine glass fibre or hair and rotated continuously on the camera axis during the exposures. Displacing the air in the camera with hydrogen is advantageous because this appreciably reduces general scatter of the X-radiation near the lower angles of diffraction. It is useful to have available two cameras of different diameters, for example, 10 cm. and 19 cm. respectively. The larger camera naturally increases the separation of the diffraction lines.

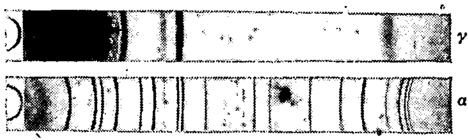
Applications of X-Ray Crystal Analysis

Identification is to a large extent achieved by comparison of the pattern of the specimen with standard X-ray patterns of known pure substances, and it is desirable to possess as large a collection as possible of standard photographs. Generally, the origin and the chemical or spectroscopic analysis of a specimen will suggest likely substances and set a limit to the possibilities, but the experience and memory of the investigator will enable much time to be saved in any given search. It would be advantageous to have a reference index in terms of interplanar spacings for as many powder photographs as possible, with a master table, for example, of two or three of the strongest lines in each. There are very considerable difficulties, however, in making the index sufficiently comprehensive.

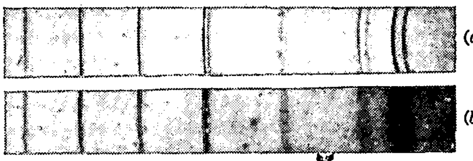
The strengths of the respective X-ray patterns from the components of a mixture are dependent upon the relative amounts present, so that a quantitative determination of composition can be made. Usually the accuracy is not very high, partly because of some uncertainty in the estimation of line intensities, but for small concentrations of one phase in another the estimation may frequently be made to 1–2 per cent.

Far from being the only application of X-ray powder photography, formal identification of a chemical compound may be but the initial step in an investigation. It is the more subtle information so readily given by the X-ray technique that is frequently of such great importance. In the first place, we often wish to distinguish between different crystalline varieties of a substance, and since it is the atomic arrangement that determines the form of the X-ray photograph, true crystalline modifications will give distinctive X-ray patterns. In the case of silica there are three polymorphic forms stable at ordinary temperatures, namely, quartz, cristobalite and tridymite. Silica bricks are employed extensively as refractories in glass and steel furnaces; the raw material is quartz and the bricks must be fired at high temperatures before use to convert most of the quartz to cristobalite and tridymite. Although the chemical composition of the brick remains unchanged, X-ray examination shows when the change in crystal form of the silica has taken place.

Mixed crystal or solid solution formation is readily revealed by X-ray powder photographs. With a continuous series of solid solutions the end members of which are isomorphous, the dispersion of the lines of the X-ray patterns usually changes systematically with composition. Such a series is formed between barium and strontium carbonates, the compounds used in the preparation of the alkaline earth oxide-coated cathodes for thermionic devices. It is often necessary to determine the composition of such oxide coatings after operation, and since the amount of material is usually extremely small and the separation of barium and strontium difficult by the more usual chemical analytical methods, X-ray analysis has been applied. The ratio of barium to strontium is determined by measuring the displacement of the X-ray pattern of the thermionic cathode coating in the form of carbonate from the patterns of the individual carbonates of strontium and barium. The study of alloys or the solid solutions formed between elements is one of the most important applications of X-ray analysis; extensive examinations have been made of ternary alloys, where complex problems of equilibrium arise and the distinction between the various phases is difficult or impossible by microscopic or other methods[5,6].



X-RAY POWDER PHOTOGRAPHS (10 CM. CAMERA, COPPER $K\alpha$ RADIATION) OF γ AND α FORMS OF ALUMINA, ILLUSTRATING LARGE DIFFERENCE IN ULTIMATE PARTICLE SIZE.



PARTS OF X-RAY POWDER PHOTOGRAPHS (19 CM. CAMERA, COPPER $K\alpha$ RADIATION) COMPARING (a) SODIUM CHLORIDE ANNEALED AT 450° C. WITH (b) SODIUM CHLORIDE AFTER SEVERE GRINDING.

If the average crystal size of a powder falls below a certain value, the lines of the X-ray pattern become broadened, and for very small crystals the lines are so broad as to be better described as diffraction bands. The amount of the broadening may be measured and used to calculate the average crystal size. Characteristic chemical or physical properties of a material may often be dependent upon ultimate crystal size rather than upon aggregate particle size. The γ form of alumina, for example, is used as an absorbent for water vapour in gas dryers, when it is frequently referred to as 'activated alumina'. The high absorptive properties are associated with the fact that this form of alumina, as usually prepared, consists of extremely small crystals, some 40–50 A. in size, the X-ray powder photograph showing very diffuse lines compared with the sharp lines on the pattern of the relatively inactive α alumina.

Broadening or diffuseness of the X-ray lines may also be associated with what is called lattice strain or lattice distortion. Such distortion is present in filings from a metal or in a powder which has been severely ground. The presence or absence of strain is best examined in the back-reflexion region of the X-ray pattern, where the normally sharply resolved α doublet lines of the characteristic radiation may become fused into a broad unresolved reflexion. It is often required to test the efficacy of heat treatments in freeing a metal from strains introduced by particular mechanical processes, and here the detection of lattice distortion by X-rays is of great practical importance. In the manufacture of alloys of nickel and iron in powdered form for use at high frequencies in various types of magnetic loading and radio cores, it is inevitable that high degrees of lattice strain are introduced and this must be reduced to a minimum to obtain the magnetic characteristics required. By examining the resolution of the lines on the X-ray patterns of powders after heat treatment at successively increasing temperatures, it is possible to determine at what stage the strain is eliminated, and so an appropriate 'annealing' schedule can be chosen. Moreover, by the examination of finished powder, variations in the manufacturing conditions are quickly revealed.

The examples given here are but a random selection from the very many and varied applications of X-ray technique. They should, however, enable some picture to be formed of the extensive manner in which X-ray methods may be utilized in the industrial laboratory.

MEASUREMENT OF RADIATION FOR MEDICAL PURPOSES*

By PROF. W. V. MAYNEORD
Royal Cancer Hospital, London

THE methods of measuring radiation for any purpose must in the end be determined by the fact that we are concerned with a form of energy. In particular, the biological or medical use of radiation is dominated by the rule that absorbed energy alone is effective, so that we are forced in considering the physical aspects of the use of radiations for these purposes to look very closely into the measurement of absorbed energy.

Considering the case of X rays first of all, it has for many years been recognized that the most promising basis on which to construct a system of measurement is the ionization produced by them in air, and since 1928 the röntgen based upon this finding has been used as the internationally accepted unit of dose. In 1937, as the result of a good deal of experimental and theoretical work, the use of the unit was extended to gamma rays, and a new definition of the röntgen was promulgated. The fundamental idea, namely, that we take all the electrons set free by the radiation from a certain mass of air, utilize as much as possible of their energy in producing ionization in air and measure the number of electrostatic units of charge thus liberated, appears much more clearly in the new definition.

Having in this way obtained a suitable unit, it was natural to apply it to medical problems, in particular to that of finding the dose at any point throughout the tissues of the body. First of all, the distribution of radiation along the axis of a beam of X rays was studied over a very wide range of conditions from 10 kv. up to some 2,000 kv., and so a large amount of useful information was collected concerning the effective penetration of the beams. Later the studies were extended to include the complete three-dimensional problems of distribution and the study of 'isodose surfaces'. Simple geometrical methods of dealing with these problems were demonstrated, and it is possible by the use of plaster casts to estimate fairly closely the dose received at any given point within any arrangement of beams of radiation, however inclined or concentrated. Alternatively, the best arrangement of beams of radiation in order to produce the maximum dose at the point desired while at the same time keeping down the dose to normal healthy tissue, may be investigated.

So far we have been concerned with the amount of radiation at a particular element of volume, but it is important to develop this study so as to estimate the total energy absorbed by the body as a whole, the estimates of energy absorption to be made if possible in absolute energy units.

It will be recognized that the röntgen is essentially a unit of energy absorption in air, the factor of proportionality depending upon the energy required to produce one ion pair. If this energy is 33 electron-volts, it follows that when 1 röntgen is delivered to 1 gm. of air there will be an absorption of energy of about 85 ergs. For soft animal tissues the value will vary a little with wave-length, but for many purposes may be assumed to be equal to this amount. For the further development of the theory it is also necessary to consider the relationship between the intensity of a beam of X or gamma rays in ergs/cm^2.sec. and the dosage-rate, that is, r./min. Evidently the relationship depends upon the wave-length of the radiation, and it is easily calculated that whereas the energy flux per cm^2. per röntgen for gamma rays is of the order of 3,000 ergs, for long wave-lengths of the order of 1 A. the corresponding number is about 30 ergs. The distinction between intensity and dosage-rate is a very important one, which is all too frequently neglected in theory and practice.

In considering some of the effects of radiation, it seems that the total energy absorbed throughout the body is a very important quantity. The distribution studies of dose, the isodose surfaces, coupled with the deduction of the energy absorbed per gm. per röntgen, enable estimates of the energy absorbed to be made. We have used as a unit the energy absorbed when 1 röntgen is given to 1 gm. of air, and called it 1 gram-röntgen. In clinical practice a megagram-röntgen is of a convenient order of size and may be shown very easily to be approximately 2 gm.cal.

Again, by geometrical and analytical methods (assuming simple laws of variation of radiation with depth) the integration of the energy absorbed throughout any part of the body may be carried out, and so the total energy absorbed may be estimated. This has been done for a number of conditions occurring in practice and it is found that the physical results are very instructive in relation to the clinical findings. As an example of the kind of problem in which the results are significant, we may quote the problems of the protection of staff and patients from unwanted radiation, where the differences now revealed in the total energy absorbed in the body as a whole per unit dose on the skin raise the question of the assumed independence of 'tolerance dose' of wave-length. By the use of large numbers of pressed bakelite - carbon condenser ionization chambers throughout a model of the body, this subject is being investigated further.

* Substance of a lecture delivered to the Physical Society on Feb. 27.

Having obtained estimates of the energy flux into the body and of the energy absorbed from beams of X and gamma rays, it is natural to attempt the corresponding solution for ultra-violet and infra-red rays. By the use of calibrated thermocouples, information on this subject may be obtained, and indeed in the case of ultra-violet light a good deal is already available. It seems that the total energy absorbed per square centimetre of the body when irradiated with ultra-violet light so as to produce a threshold erythema is of the same order as that given when 100 r. of medium wave-length X rays is administered. For infra-red radiation very little information was available, but we have used suitably mounted calibrated vacuum thermocouples (General Electric type) and made measurements of the intensities required for a painful sensation and of the intensities normally employed in therapy. The values of these quantities are found to vary with the colour temperature of the source, the normal intensity for a 500-watt tungsten filament lamp in a reflector being of the order of 1·5 gm.cal./cm^2.min.

Finally, then, we see the order of intensities and amounts of energy involved in the use of different kinds of radiations.

(*a*) Type of radiation.			Intensity in ergs/cm.^{2}sec.
High-voltage X rays. Heavy filter	200 kv.	40 r./min.	2×10^3
Ultra-violet light		20 μ watts/cm.^{2}	2×10^8
Infra-red		1 gm.cal./cm.^{2}min.	7×10^5

(*b*) Type of radiation			Total energy absorbed
High-voltag e X rays	200 kv.	30 megagram-röntgens.	60 gm.cal. in 6 weeks.
Ultra-violet light		Erythema over body surface of 1,500 cm.^{2}.	8 gm.cal. at a sitting.
Infra-red		1 gm.cal./cm.^{2}min. 20 min. Area 1,500 cm^2.	3×10^4 gm. cal. at a sitting.

The intensities are approximate but of interest in the correlation of all the radiations on an energy basis.

OXIDATION OF HYDROCARBONS AT LOW TEMPERATURES

By P. GEORGE, PROF. E. K. RIDEAL, F.R.S., and A. ROBERTSON

Department of Colloid Science, Cambridge

FARMER and Sundralingam in a recent paper[1] have stressed the part that hydroperoxides play as the first isolatable intermediates in autoxidations: their investigation, anticipated by Criegee, showing that olefin peroxides have the structure $-CH(OOH)-CH{=}CH-$, brings these peroxides into line with Rieche's alkyl peroxides, possessing the reactive group ($-OOH$). The work reported below on the uncatalysed and the heavy-metal catalysed oxidation of alkyl benzenes and long-chain saturated aliphatic hydrocarbons (C_{15} to C_{25}) in the liquid phase at 100–120° C., also supports the hypothesis that hydroperoxides are primary oxidation intermediates.

The Chain Character of the Reaction

In the case of alkyl benzenes the peroxide found after reaction corresponds to 60–80 per cent of the oxygen absorbed. The peroxides of long-chain paraffins are not so stable; and they are only found in small concentration, about 5 per cent. In the metal-catalysed oxidation good agreement is obtained between the observed peroxide concentration and that calculated from the efficiency of the catalyst in peroxide decomposition.

In the catalysed oxidations a curious independence of oxidation-rate of catalyst concentration was found above a certain value. This has been reported in other autoxidations, notably benzaldehyde catalysed by ferrous phthalocyanine[2] and linseed oil catalysed by hæmoglobin[3]. The explanation advanced was low oxygen availability due to physical conditions. This cannot be the case here, for the rate of oxidation has been found proportional to the partial pressure of oxygen. The curves obtained for long-chain paraffins catalysed by cobalt stearate and ethyl benzene catalysed by copper stearate are shown in Fig. 1.

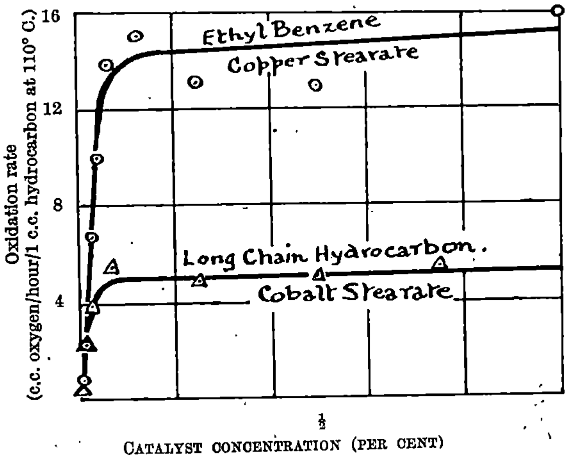

Fig. 1.

This can be explained by the hypothesis of a chain mechanism in which the metallic catalyst both starts and stops chains. This gives the expression:

$$\text{Rate of oxidation} = \frac{a + bY}{c + dY} \quad . \quad . \quad . \quad (1).$$

Y is the catalyst concentration, a the number of chains started per unit time in the uncatalysed reaction, b the number started per catalyst molecule $1/c$ and $1/(c + dY)$ the uncatalysed and catalysed chain lengths respectively.

The chain character of the oxidation has been demonstrated by inhibition with β-naphthol. It causes a marked diminution in the oxidation rate of alkyl benzenes, the rate slowly increasing with time. For catalysed long-chain paraffins complete induction periods lasting for 2–6 hours with no measurable oxygen uptake are observed, even with a 2–50 molar excess of catalyst over inhibitor. Equations have been developed to calculate the chain length from this diminished rate or induction period data. A surprising specificity of catalysts is shown by the following experimental results:

(*a*) Copper stearate catalyses the oxidation of ethyl benzene and tetralin, but not long-chain paraffins, whereas cobalt stearate is as efficient a catalyst for all three.

(*b*) Copper stearate added to cobalt-catalysed long-chain paraffin diminishes the rate.

(*c*) Copper stearate diminishes the uncatalysed rate of octene mixtures.

All these phenomena are explicable on the assumption of different chain-starting and chain-stopping efficiencies. From equation (1), if b/d is *greater* than a/c, then the metal is a positive catalyst, whereas if b/d is *less* than a/c it is an inhibitor.

Farmer[1], Cook[4] and others have shown that heavy metal catalysts decompose hydroperoxides giving mainly ketones and alcohols. Kinetically, the decomposition of tetralin peroxide is unimolecular, the reaction constant being proportional to catalyst concentration. This suggests a 'metal catalyst hydroperoxide complex' breakdown. The efficiency of a catalyst as a chain stopper is paralleled by its effect as a catalyst in the decomposition of hydroperoxides. A kinetic study suggested that in catalysed oxidations the relation

$$\frac{dx}{dt} P = \alpha Y$$

should hold, where $\frac{dx}{dt}$ is the rate of oxidation, P the equilibrium peroxide concentration and Y the catalyst concentration. This was found to be so. The constant α gives a measure of peroxide reactivity.

The Oxidation Intermediates

In the case of long-chain paraffins, the following experiments indicate that these alkyl hydroperoxides decompose almost exclusively to give ketones.

Both primary and secondary alcohols have a very slow oxidation-rate compared with other long-chain derivatives. The following oxidation rates are measured at 110° C. and are in cubic centimetres oxygen per hour per 1 c.c. solution.

Type of compound	Uncatalysed rate	Catalysed rate with ½ per cent cobalt stearate
Sec. octyl alcohol ...	0·06	0·2
Cetyl alcohol	0·08	0·8
Long-chain paraffin ...	0·25	4·5
Laurone	2·6	8·6
Stearic acid	0·5	9·0

If alcohols were intermediates, the oxidation would tend to slow down markedly and alcohols would preponderate in the product. Furthermore, by oxidizing a mixture of hydrocarbon with a secondary alcohol (the type of alcohol produced by oxygen attack on a $-CH_2-$ group) ketone or acid, the results shown in Fig. 2 are obtained.

It is apparent that secondary alcohols inhibit the oxidation of hydrocarbons just as β-naphthol does, though not to such a marked degree; 10 per cent of alcohol produces an induction period of at least 6 hours and 25 per cent for at least 24 hours. This is very strong evidence that the oxidation does not proceed via alcohols, and so Bone's hydroxylation theory does not apply in these low-temperature liquid phase oxidations. The curves for acid and ketone mixtures indicate that these are also chain processes. The shape of the ketone-hydrocarbon curve indicates that the ketone oxidation chain-length is greater than the hydrocarbon oxidation chain-length. The converse holds for the acid-hydrocarbon curve.

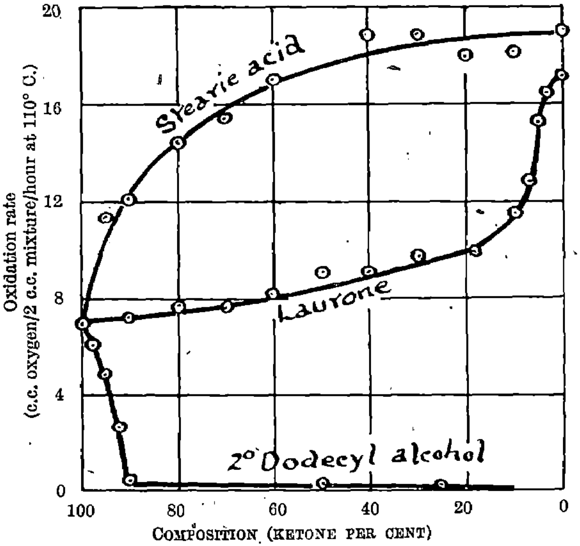

Fig. 2.

The Nature of the Catalyst

The function of the metallic catalyst in hydrocarbon oxidation is thus shown to be threefold: to start and stop reaction chains leading to the production of hydroperoxides, and to decompose the peroxides. It has been suggested in the past that the catalytic activity is due to the heavy metal ion. However, a vast number of co-ordination compounds act as catalysts[5], among them porphyrins[6] and phthalocyanines[2], and the assumption that their varying catalytic activity is due to their differing degrees of electrolytic dissociation is contrary to their physical properties and stereo-chemical behaviour. The real problem now is to decide which of the transition element properties—whether complex formation or valency change—is responsible for the chain-starting and chain-stopping process. The rates of the catalysed oxidation of tetralin and paraffinic hydrocarbons are proportional to the partial pressure of oxygen, which implies that the oxygen molecule is involved in the chain-starting process. This favours complex formation. A study of some sixty catalysts suggested that all the good catalysts are ionic complexes, which would be the case if the required bonding of the oxygen molecule were similar to that in oxyhæmoglobin, where paramagnetic hæmoglobin combines with paramagnetic oxygen giving diamagnetic oxyhæmoglobin[7].

In an attempt to poison this heavy metal catalysis with carbon monoxide, it was found to be oxidized to carbon dioxide[3]: control experiments showed this to happen only in the presence of oxidizing hydrocarbon. It is hoped that this will help in the future to elucidate the chemical nature of the chain process.

SCIENCE AND ART AT THE ROYAL ACADEMY, 1942

By DR. A. T. HOPWOOD
British Museum (Natural History)

WHEN reviewing last year's Summer Exhibition at the Royal Academy, I ventured to say that since intellectual honesty is at the foundations of both science and art, there is no fundamental distinction between them, and that apart from the objectivity of the one and the subjectivity of the other the differences are mainly those of design, of technique, and of the medium of expression. I did not attempt to define what art is because there is so much difference of opinion among professional critics, to say nothing of the disagreements to be found among painter-writers, that it seemed presumptuous for a zoologist to try to do so. On the other hand, it is but just to the artist that the critic should explain his methods so far as in him lies, and this entails an effort to define his terms.

Now a painting, a drawing, or a piece of sculpture is a report on its maker's activities. It differs from a scientific report because it records the emotions of its author, and also reveals his personality. The more sincere it is, the more complete will be the revelation of the artist's emotional personality; if this is not so the result is meaningless. When looked at intelligently, and there is a great difference between looking at an object and understanding it, it becomes a work of art to the degree in which it succeeds in conveying the artist's meaning to the mind of the beholder.

For example, at the present Exhibition "Stone Walls, Yorkshire" by Sidney Lee (No. 103) is to me a work of art because it conveys the feeling and spirit of the landscape in the Millstone Grit regions of the Pennines; but if another fails to respond to the picture, then not all the technical merit in the world will make it a work of art for that person. Again, "The Coaster" by Arthur B. Cornwell (No. 323) is likewise a work of art for much the same reason; it makes an immediate appeal to all sailors and also conveys a vivid impression of stormy coastal waters of Great Britain to those unfamiliar with them in a way that no photograph could ever do. The artist has succeeded in capturing the mood of the storm and recording it in paint. These are simple examples, but what is to be made of "Wet Fish on Tilted Tray" by Frank Goulding (No. 332)? Here we are confronted with the adumbration of a number of forms which the artist avers to be fish; fish, be it said, such as no fisherman ever saw. What then was the intention of the artist? It may be that this is a report on some experiment which I cannot understand, but it is certain that it conveys nothing to me, and therefore is not a work of art for me.

Art, then, depends on the co-operation of two persons, the artist and the spectator. When the artist succeeds in expressing the emotional imagery conjured up in his mind by a given set of circumstances in such a way that their depth and intensity are communicated to the spectator, he has achieved art. But the spectator, too, must do his share, for, to quote Sir Joshua Reynolds, "It is the lowest style only of the arts that may be said in the vulgar sense to be naturally pleasing. The higher efforts of those arts do not affect minds wholly uncultivated". Which is not so far removed from Mr. Roger Fry's dictum that "In proportion as art becomes purer the number of people to whom it appeals gets less and less. It appeals only to the æsthetic sensibility, and that in most men is comparatively weak".

If the current Exhibition is approached in some such frame of mind as that indicated in the preceding paragraphs; if the scientific man will visit the Royal Academy with the intention of examining the pictures instead of just going to see them, he will find plenty to interest him. For the zoologist it is easy, and not very clever, to walk round noting that "Peregrine Falcon" by C. F. Tunnicliffe (No. 397) is not correctly coloured; that the pochard in "Good Companions" by Jessie Hodge (No. 391) has a lack-lustre eye; and that a Suffolk Punch, or what appears to be intended for such, is scarcely an appropriate mount for a cavalryman (No. 752). The botanist will find numerous flower pieces to criticize but very little fruit or vegetables. As for the war pictures, they are of general interest. There are portraits for the social historian; aeroplanes for the aeronautical engineer; ships for the navigator; bomb-scarred buildings for the architect and town-planner; and so on. Many of these reach a high level of competence, indeed as reporting they are often first-rate, but the damning entry "Painted for the Nation's War Records" attached to some of them explains a lot, and probably "Painted as a War Record" should be attached to the majority. They often lack inspiration and feeling.

Two war pictures are an exception. Ugly in themselves, unpleasant in colouring, and inaccurate in drawing as they are, they are perhaps the most successful works in the whole Exhibition. These pictures are: "Clydebank; a Tribute", by Hugh Crawford (No. 108) and "Military Objectives" by Louis Duffy (No. 183). The first conveys the doggedness of the civil population in war-time, and the second the dull misery of the bereaved. These are symbols, poignant symbols, of the horrors of aerial bombardment, and as such their essential truth is startling and vivid. Where these two artists have triumphed, Charles Wheeler has failed. His allegory, "Wings" (No. 128), is confused alike in message and design. The winged figure to the left does not carry the conviction of the angels of Fra Angelico, or, for that matter, of the devils of Dürer and Martin Schongauer, all three of whom believed in their images; but one doubts whether Mr. Wheeler believes in his.

On the whole, however, the psychologist probably has the lion's share of this Exhibition, as of many others. He will soon discover that A. J. Munnings is so interested in figures, particularly horses and their riders, that almost any sort of a smudge will do for the rest; "Start at Newmarket" (No. 1) and "A Swimming Pool" (No. 115) illustrate this point. Gerald Kelly is obviously interested in people, but not to the detriment of their setting; indeed the care with which the quiet backgrounds are painted only serves to emphasize the importance to be attached on the subject, and the unobtrusive prominence accorded to the hands indicates his confidence and skill. Augustus John shows himself still to be a romantic at heart, more at home with a subject such as "The Mask" (No. 106) than with an official portrait (No. 110). So one might go on through the catalogue, and so the visitor should go on for himself.

Most of the exhibits in the Architectural Room are of public buildings. The most interesting are the drawings of some portions of the Anglican and Roman cathedrals at Liverpool by Sir Giles Gilbert Scott and Sir Edwin Lutyens respectively; they are hung side by side (Nos. 704 to 708) so that comparison is made easy. Plans for domestic dwellings are few, but protest must be made against No. 666, "War-time Housing on the Wirral"; not even war-time can excuse the mechanical dullness of these brick boxes.

Much of the sculpture is pleasant and intimate although not profound. Particular mention may be made of "Head of Young Bull" by Georg Ehrlich (No. 817), the "Leopard" by Hermon Cawthra (No. 796), and "Siamese Cat" by Margaret Heaton (No. 820). "Cart-horse Lying Down" by Tonie Brignall (No. 818) is stylized but not unsuccessful.

On the whole, then, there is little of primary scientific interest in this year's Academy, but this is all to the good. The natural reaction to a picture of 'scientific interest' is to examine it for its accuracy—the science comes before the art; but this year science takes a back seat and her devotees can give themselves up to the pleasure of getting on good terms with the exhibits and, through the exhibits, with their authors. Viewed in this light, the Summer Exhibition of the Royal Academy of Arts, 1942, is very much to be commended.

OBITUARIES

The Rev. T. E. R. Phillips

It is with great regret that we record the death of the Rev. T. E. R. Phillips, so soon after the University of Oxford had conferred on him an honorary D.Sc.

Theodore Evelyn Reece Phillips, the son of the late Rev. Abel Phillips, was born on March 28, 1868, and was educated at Yeovil Grammar School. He proceeded later to St. Edmund Hall, Oxford, and graduated B.A. in 1891, in which year he was ordained to the curacy of Holy Trinity, Taunton. He took his M.A. in 1894 and two years later, while curate at Hendford near Yeovil, he used a 9¼-inch altazimuth reflector for the systematic observation of the planets, especially Mars and Jupiter. This work was continued when he moved to Croydon, and when he was appointed curate at Ashtead in 1906 a 12¼-in. equatorial reflector by Calver was substituted for the 9¼-in. An 8-in. refractor by Cooke, which was lent to him by the Royal Astronomical Society in 1911, was used for about thirty years, chiefly for double-star work.

In 1916 Phillips was appointed rector of Headley, and he set up an observatory in the rectory glebe where, in addition to the instruments referred to, an 18-in. reflector (mirror by With), lent by the British Astronomical Association, was mounted on the equatorial stand which had previously carried the 12¼-in. reflector. This 18-in. reflector was used mostly for planetary work and especially for investigating the surface currents on Jupiter.

A short record of Phillips's work on the planets, double-star measurements and light curves of long-period variables appeared in NATURE of February 28 (p. 241), and it is unnecessary to repeat this. Some reference may be made to his analysis of the light-curves of long-period variables, which he undertook on the suggestion of the late Prof. H. H. Turner about thirty years ago. He conducted a harmonic analysis of the light-curves of nearly eighty stars, and a full account of this appeared in his second presidential address to the British Astronomical Association (*J. Brit. Ast. Assoc.*, 27, 1; 1916). In this address he referred to his work on *S.* Herculis (*Mon. Not. Roy. Astro. Soc.*, **75**, 7), where he had gone as far as the fifth harmonic. He felt that certain assumptions were adding encumbrances to the problem and remarked ". . . we have now reached a stage when the theory of stellar variation calls for reconsideration and revision".

In addition to his interest in planetary features, variable stars and double stars, Phillips was a keen meteorologist and was elected a fellow of the Royal Meteorological Society in 1918. He kept an unbroken record of daily temperature and rainfall at Headley for twenty-five years and was working on the results before his death. He was analysing harmonically a large number of temperature curves for the British Isles and hoped to publish the results after the War. He was also interested in botany, more especially in British and Alpine flora, as well as in sketching, and he took an active part in the preservation of the countryside.

Phillips was a member of Commission 16, which is specially concerned with the physical study of the planets, of the International Astronomical Union, and was president for some years. In 1922 he was appointed by the late Archbishop Davidson as his representative on behalf of the Church of England to consider the stabilization of Easter. Later he sat on the special committee of six formed by the International Union to consider calendar problems in general. For many years he was a university extension lecturer for Oxford, Cambridge and London, and also Gilchrist Trust lecturer. In connexion with the British Astronomical Association he was director of the Jupiter Section, 1900–33, director of the Saturn Section, 1935–40, president during 1914–16, and recipient of the Walter Goodacre Medal and Gift in 1930. In 1918 the Royal Astronomical Society awarded him the Jackson-Gwilt Gift and Medal. He was secretary of the Society during 1919–26 and president during 1927–29. In February of this year, Oxford conferred on him the degree of D.Sc. *honoris causa*, an honour which he greatly appreciated.

His published works include his revision of Ball's "Popular Guide to the Heavens", and "Astronomy and Modern Thought". In addition to these, he collaborated with Dr. W. H. Steavenson in editing "Splendour of the Heavens", 2 vol., and he contributed articles in the "Encyclopædia Britannica" on "Planets".

Phillips's genial disposition made him very popular in astronomical circles, where he will be greatly missed. During his illness many anxious inquiries were made about his progress and there were hopes that he might rally and attend the meetings again, but early in May it was known that his condition was extremely grave, and he died on May 13. The interment took place at Headley on May 16, when a number of astronomical and other friends were present. In 1906 he had married M. H. Kynaston, who, with a son, survives him. M. DAVIDSON.

Mr. W. A. Douglas-Rudge

WE regret to record the death, on February 14, of Mr. W. A. Douglas-Rudge, late science master of Rugby School. Mr. Douglas-Rudge was a scholar of

St. John's College, Cambridge (B.A., 1899; M.A., 1903), where he obtained a first class in Part I of the Natural Sciences Tripos. He was science master of Woodbridge School from 1903 until 1907, when he was appointed professor of physics at University College, Bloemfontein. During his residence in South Africa he made a special study of atmospheric electricity in that part of the world. Several of his papers were published in the *Transactions of the Cambridge Philosophical Society*. He returned to Great Britain and was appointed science master at Rugby in 1916, a post which he held until his retirement at the end of 1930. Many of his old students at Woodbridge, Bloemfontein and Rugby will remember with gratitude his inspiring lectures, which were always illustrated with many experiments.

NEWS and VIEWS

U.S. National Academy of Sciences: Elections

The following elections were made at the annual meeting of the U.S. National Academy of Sciences held during April 27–28: *Foreign Secretary* (to succeed the late Prof. L. J. Henderson): Prof. Walter B. Cannon, Harvard Medical School, Boston, Massachusetts (term: four years ending June 30, 1946); *New Members of Council*: Prof. George W. Corner, professor of anatomy, Strong Memorial Hospital, Rochester, N.Y.; *Foreign Associate*: Prof. Robert K. S. Lim, professor of physiology, Peiping Union Medical College, Peiping.

Members of the Academy: Prof. Homer Adkins, professor of chemistry, University of Wisconsin, Madison, Wisconsin; Dr. Lyman J. Briggs, director, National Bureau of Standards, Washington, D.C.; Prof. H. T. Clarke, professor of biochemistry, Columbia University, New York City; Prof. Ralph E. Cleland, Indiana University, Bloomington, Indiana; Prof. C. H. Danforth, professor of anatomy, Stanford University, California; Prof. C. A. Elvehjem, professor of agricultural chemistry, University of Wisconsin, Madison, Wisconsin; Prof. Michael Heidelberger, professor of biochemistry, Columbia University, New York City; Prof. John Gamble Kirkwood, Cornell University, Ithaca, New York; Dr. Paul D. Merica, metallurgist, 67 Wall Street, New York City; Dr. Thomas Midgley, jun., chemist, Worthington, Ohio; Prof. Francis D. Murnaghan, professor of applied mathematics, Johns Hopkins University, Baltimore, Md.; Dean John T. Tate, professor of physics, University of Minnesota, Minneapolis, Minnesota; Prof. Alfred M. Tozzer, professor of anthropology, Harvard University, Cambridge, Massachusetts; Prof. E. E. Tyzzer, George Fabyan professor of comparative pathology, Harvard Medical School, Boston, Massachusetts; Prof. S. A. Waksman, professor of soil microbiology, Agricultural Experiment Station, New Brunswick, New Jersey. Prof. Albert Einstein, professor of mathematics, Institute for Advanced Study, Princeton, New Jersey, was also elected a member; his status as a foreign associate, dating from 1922, before he became an American citizen, will not be affected by the new election.

History of Science in Scotland

The Regional Committee for Adult Education of the University of St. Andrews has followed up the issue of twelve pamphlets on "Britain and its People" by the publication of a further dozen under the general title "Scotland and its People". These pamphlets provide, in a very readable form, much general information about Great Britain, and particularly about Scotland. Through the help of the Pilgrim Trust, it has been possible to distribute them free of charge to members of H.M. Forces and Allied troops. Among the titles in the second series are "The History of Science in Scotland", by Sir D'Arcy Thompson, "Scotland and Advances in Medicine and Surgery", by Dr. J. Patrick, "The Scottish Universities", by Sir James Irvine, and "Scottish Agriculture and Industry", by Mr. J. W. Nisbet. In his rapid survey of Scottish science Sir D'Arcy Thompson points out that Napier of Merchiston was the first true man of science in Scotland since Michael Scot. Soon after Napier's death, began the long line of "academic Gregories", contributing some fourteen professors of mathematics, medicine and chemistry to the Scottish universities during the succeeding two hundred years. "There is hardly such another instance known of scientific heredity, unless perhaps that of the Cassinis, who directed the Paris Observatory for nearly as long." John Napier, James Gregory, Colin Maclaurin and James Stirling are characterized as the four great Scottish mathematicians; "but there came after them many a good man", including Ivory and Tait.

Among outstanding figures in chemistry are Black, Graham, Couper, Dewar, Ramsay and James Young; in physics and engineering, emphasis is laid upon Watt (whom Davy likened to Archimedes), Robison, Russell (the builder of the *Great Eastern*), Brewster, Clerk Maxwell and Lord Kelvin. Of the last-named Sir D'Arcy writes: "Somehow he is not quite so great, he is not near so lovable, as Clerk Maxwell; but his achievements were in touch with the spirit of his time, and his fame was prodigious." In astronomy, John Lamont of Braemar became Johann von Lamont, head of the Munich Observatory and an authority on terrestrial magnetism, and with him are mentioned Broun, Buchan and Henderson. Geology is represented by James Hutton, 'the father of modern geology', and many another; for "Scotland has done so much for geology that this science seems peculiarly her own". Finally, in natural history and botany we encounter Sir Robert Sibbald, founder of the Edinburgh medical school, Goodsir the anatomist, Edward Forbes, Wyville Thomson, and Robert Brown of Montrose—Humboldt's *facile princeps botanicorum*. One lays down this attractive and admirable account with a lively sense of the truly remarkable nature of Scotland's contribution to pure and applied science.

Irish Sea and Inland Fisheries

A very satisfactory state of affairs is shown in the report of the Minister for Agriculture (Eire) on the sea and inland fisheries for 1940. The yield of sea fish exceeded that of any year since 1930 and was appreciably larger and of greater value than in 1939. The position has been affected materially by the work of the Irish Sea Fisheries Association, Ltd., which began to function in 1931, and during the period intervening was engaged in the provision and equipment, on hire-purchase terms, of more than 130 motor-vessels which constitute the bulk of the existing fishing fleet. The larger landings in the year are attributable mainly to the efforts of the inshore fishermen, who found themselves well equipped at the onset of war conditions which have caused such a radical change in the operation of supply and demand for the output of sea-fishing in common with other food-producing industries. The increased earnings now obtainable are attracting more and more men.

The Dingle fishermen again did remarkably well, and their landings were just double the value of those of the preceding year. The summer and winter herring fishery, contrasted with 1939, showed quantitative increases of 21 per cent and 56 per cent respectively. The catches of salmon and sea-trout are better than those of the three preceding seasons, but are still below the average for the previous four decades. The drift-net fishings for salmon off the north and north-west coasts were also below average. The spawning season was a good one in nearly all fishing districts and the run of smolts, so far as was ascertainable, up to the average of previous years. The bad weather, however, interfered seriously with hatching experiments, although the output from the experimental brown trout hatchery at Lough Owel was nevertheless the highest yet recorded.

Meteorology in Iraq

THE fifth annual report of the Director of the Meteorological Service of the Government of Iraq, which covers the year ending March 31, 1941, describes the work of this Service during a period when it was much affected by the entry of Italy into the War on June 10, 1940. The amount of civil aviation in Iraq was greatly reduced, but the companies still carrying on were supplied with reports and forecasts on the usual lines. The greatest difficulties arising from the entry of Italy into the War were in connexion with supplies of equipment from Great Britain. The supply of balloons required for making observations of the upper winds became erratic, and larger reserves had to be built up, which gave rise to problems of storage in a climate very unfavourable for rubber storage. The experiment was made of getting balloons made in Australia and the United States. In both cases results were satisfactory apart from the extra expense.

Other innovations included the making of the hydrogen required for the balloons on the spot with the aid of French generators employing ferro-silicon, and the construction by the Ordnance Department of Stevenson screens and rain-gauges, the former at a cost less than half that involved when obtaining the screens from England. What is described as the outstanding event of the year under review was the setting up of synoptic reporting stations at Hail and Riyadh in Saudi Arabia with the help of King Ibn Saud. A new observatory was also established at Kut al Hai, and a Dines pressure tube anemometer was installed at Rutba at considerable expense. A beginning was made with the preparation for publication of all available climatological data based on observations made in Iraq. The report, therefore, shows that the year was one of progress in spite of the unusual difficulties in the way of advance.

The Ray Society

THE report of the Council of the Ray Society, which has just been circulated, states that, with the consent of the members, the annual general meeting has again not been held, and the present officers and council will continue to act for the current year. The accounts show that the reduction in the amount received from subscriptions has again been less than was anticipated and the sales of the Society's publications have been well maintained. A volume on "The Larvæ of Decapod Crustacea" by Dr. Robert Gurney will shortly be issued to subscribers for 1941. A work on the British Mysidæ (Opossum shrimps) by Prof. W. M. Tattersall is in preparation and is intended to form the issue for 1942. Owing to shortage of materials, the publications will, for the present, be issued in paper covers, but it is hoped later to supply covers for binding uniform with the volumes already published. The Council reminds members that, under present conditions, considerable delay in the publication of the annual volumes cannot be avoided. It is mentioned that at least one author has lost, by enemy action, all the notes and manuscripts prepared for a work to be offered to the Society.

Diseases and War

THE April issue of the *Quarterly Review* contains an interesting article on this subject by Major Frederic Evans, who discusses the problems of an army so far as the maintenance of health is concerned. He classifies the diseases which it is important to prevent in the following nine groups: (1) louse-borne diseases, which consist of typhus fever, trench fever and relapsing fever, (2) mosquito-borne diseases, namely, malaria and yellow fever, (3) diseases caused by sandflies in hot regions, such as sandfly fever, oriental sore and probably kala-azar, (4) excremental diseases, namely, typhoid, paratyphoid, cholera, dysentery and infectious diarrhœa, (5) diseases due to droplet infection, such as cerebro-spinal fever, diphtheria, scarlet fever, measles, smallpox, influenza and pulmonary tuberculosis, (6) venereal diseases and skin diseases, especially scabies, (7) diseases caused by environmental conditions, namely, heat stroke, frostbite and trench foot, and (8) food deficiency diseases, such as scurvy, beriberi and night-blindness. In conclusion, Major Evans emphasizes the importance of the medical officer training his sanitary duty squad as thoroughly as he trains his stretcher bearers and medical orderlies.

The Far East and the War

PROF. P. M. ROXBY's admirable pamphlet on "China" (Oxford Pamphlets on World Affairs, No. 54. London: Oxford University Press. 4*d*. net) provides an excellent introduction, for those who have only now come to realize the importance of China in the War, to an understanding of the place of China in the struggle of the United Nations. Within the compass of thirty pages, he gives a succinct description of the land of China, the impact thereon of the West, and of the Nationalist movement and the progress of reconstruction up to 1931. The latter part of the pamphlet deals with the Japanese seizure of Manchuria and the consequences of the Sino-Japanese war which broke out in 1937. With Sir John Pratt's "Japan and the Modern World" (Oxford Pamphlets on World Affairs, No. 55. 4*d*. net) a penetrating analysis is afforded of the causes which have merged the European and the Far Eastern conflicts into a single war. Sir John Pratt, moreover, in tracing the course of Japanese foreign policy and particularly of Japanese relations with Great Britain, goes to those fundamental differences in national temper and outlook which explain the present hostility of Japan and Great Britain, and indeed raise the question as to the desirability from the start of the Anglo-Japanese Alliance of 1902.

The Indian Science Congress

The following have been elected presidents of the various sections of the 1943 session of the Indian Science Congress, to be held in Lucknow during January 2–8, 1943. The fourteen sections into which the Congress originally divided its work have been regrouped into twelve sections. *Mathematics and Statistics*, Dr. S. C. Dhar, University of Nagpur; *Physics*, Dr. H. J. Bhabha, Indian Institute of Science, Bangalore; *Chemistry*, Dr. S. S. Joshi, Benares Hindu University; *Geology and Geography*, Lieut.-Colonel E. A. Glennie, Survey of India, Dehra Dun; *Botany*, Dr. K. Biswas, Royal Botanical Garden, Sibpur, Calcutta; *Zoology and Entomology*, Dr. B. N. Chopra, Zoological Survey of India, Calcutta; *Anthropology and Archæology*, Dr. N. Chakravarti, Archæological Survey of India, New Delhi; *Medical and Veterinary Sciences*, Dr. F. C. Minett, Imperial Veterinary Research Institute, Mukteswar; *Agricultural Sciences*, Rao Bahadur Y. Ramchandra Rao, Imperial Council of Agricultural Research, New Delhi; *Physiology*, Dr. B. Narayana, P.W. Medical College, Patna; *Psychology and Educational Science*, Dr. B. L. Atreya, Benares Hindu University; *Engineering and Metallurgy*, Prof. K. Aston, Indian Institute of Science, Bangalore.

Night Sky in June

New moon is on June 13d. 21h. 02m. U.T., and full moon on June 28d. 12h. 09m. Lunar conjunctions with the planets occur as follows: Venus on June 10d. 05h., Venus 2° N.; Saturn on June 12d. 08h., Saturn 3° N.; Mars on June 17d. 07h. Mars 4° N. On June 29d. 20h. Venus is in conjunction with Uranus, Venus 1·7° S. Mercury is near the sun during the month and souths at 13h. 03m. and 10h. 39m. at the beginning and end of the month respectively. Venus is a morning star and souths at 9h. 22m. in the middle of the month. Jupiter, in conjunction with the sun on June 25, is too close to the sun to be observed. Saturn is a morning star and souths at the end of the month at 9h. 49m. Only two occultations occur in the month and the brighter of the two stars, 44 Virginis, occulted on June 22d. 22h. 50m., is mag. 5·9. The sun enters the sign of Cancer on June 22d. 01h., the summer solstice, and at this time the nights in the latitude of London are about 7 hours long. If civil twilight is taken into consideration (sun 6° below the horizon) the time of darkness is only 5½ hours. Conditions for seeing the night skies are very much restricted during the month.

Recent Earthquakes

A strong earthquake was reported on May 23 to have occurred in Colombia, South America. The town of Girardot, some sixty miles south-west of Bogota, is stated to have been partly destroyed, and shortly afterwards the island of Gorgona, in Buenaventura Bay, was submerged by a huge wave. This part of South America is particularly liable to experience earthquake shocks. Many of these from 1763 until 1936 have been described by J. Emilio Ramirez, S.J., and one reported by the British Association Seismological Committee in 1907 broke submarine cables off the mouth of the Esmeralda River on January 31, 1906.

The Ecuador earthquake of May 14 was beautifully recorded on the E-W Milne-Shaw seismogram obtained by Rev. J. P. Rowland, S.J., at Stonyhurst College Observatory. The *P* wave was impulsive at 02h. 25m. 50s. U.T. and a full suite of pulses followed. The readings are in agreement with the statements in Nature of May 23, p. 578.

Announcements

Sir Henry H. Dale, president of the Royal Society, will retire from the post of director of the National Institute for Medical Research on September 30. To succeed him the Medical Research Council has appointed Prof. C. R. Harington, who is at present professor of chemical pathology in the University of London and director of the Graham Medical Research Laboratories in University College Hospital Medical School.

Dr. C. G. Darwin, director of the National Physical Laboratory, has been appointed scientific adviser to the Army Council.

The following officers of the Royal Society of South Africa have recently been elected: *President*, Prof. A. Brown; *Hon. Treasurer*, Prof. R. W. James; *Hon. General Secretary*, Dr. A. J. H. Goodwin; *Hon. Editor of Transactions*, Dr. A. L. du Toit; *Hon. Librarian*, Prof. E. Newbery.

The following appointments in the Colonial Service have recently been made: Mr. C. E. J. Biggs (senior agricultural officer, Uganda), deputy director of agriculture, Tanganyika; Mr. A. E. Pound, (inspector of produce, Nigeria), agricultural officer, Kenya.

The population of Peru, according to the last official census, taken in 1940, is 7,023,111 inhabitants (*Bol. Of. San. Panamericana*, January). The female population forms 50·58 per cent, and the male 49·42 per cent. More than half the population, 52·89 per cent, are whites or mulattoes, and 45·86 per cent are Indians, while the Negroes constitute only 0·47 per cent.

In "Belgium and the War" (Oxford Pamphlets on World Affairs, No. 56. 4*d.*), Prof. G. N. Clark describes the economics and politics of Belgium before the German invasion of May 1940, as well as the course of Belgian foreign policy in recent years. The latter part of the pamphlet describes the brief campaign of eighteen days and the reasons for the capitulation of the Belgian army; with, finally, an account of the occupation of Belgium, colonial resistance and of the issues which have made the Belgians carry on the struggle against the Axis Powers.

Erratum. In the letter "2-Aminofluorene as Growth Inhibitor for Bacteria and Rats" by F. Bielschowsky and Prof. H. N. Green in Nature of May 9, p. 526, an error in the legend to the graph was overlooked. It should read: "broken line, feeding on 2-acetyl aminofluorenone; crossed line, 2-acetyl aminofluorene".

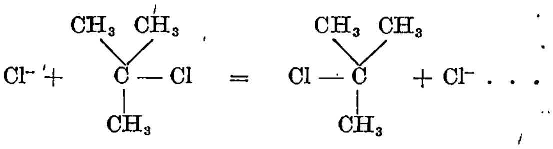
The Editors do not hold themselves responsible for opinions expressed by their correspondents. No notice is taken of anonymous communications.

Calculation of Steric Hindrance

It seems possible to account for the steric effect of non-reacting groups on substitution rates on the lines of the following scheme, illustrated here by the example of the symmetrical substitution of *t*-butyl chloride by chlorine ions :



$$\mathrm{Cl^- + (CH_3)_3C{-}Cl = Cl{-}C(CH_3)_3 + Cl^-} \quad \ldots (1)$$

In the transition state, the four *t*-butyl carbons will be co-planar and the methyl groups will cause least obstruction if arranged in either of the two symmetrical positions one of which is shown in Fig. 1. This is represented in terms of a Fisher model in which the carbon atoms have the usual covalent radii of 0·77 A. and the van der Waals' radii of 1·5 A., while the corresponding values for the hydrogen atoms are 0·32 A. and 1·2 A. respectively. The valencies of the central carbon atom are co-planar, with an angle of 120° between them ; the valencies of the other carbon atoms are at the tetrahedral angle. The position of the chlorine particles in the transition state will be such that the line joining their centres to that of the central carbon will be perpendicular to the plane of the carbon atoms. Further, the carbon chlorine internuclear distances will be equal. From the latest calculation of the transition state, this carbon chlorine distance has been found to be 2·3 A., which is practically equal to the sum of the covalent radius of carbon and the ionic radius of chlorine. These chlorine particles will have a van der Waals' radius of 1·8 A.

While a more detailed consideration, on which we will report elsewhere, shows that the presence of hydrogen atoms on the central carbon (as in the reaction $Cl^- + CH_3Cl$) does not obstruct the approach of the chlorine particles to the required distance, their replacement by methyl groups as in reaction (1) does cause an obstruction. The extent of this obstruction is indicated in Fig. 1, where the shaded sections show the areas over which penetration of the hydrogen atoms by the chlorine particle occurs. The distances between the centres of these obstructing hydrogen atoms and the centre of the chlorine particle can be calculated as 2·43 A., which is 0·57 A. less than the sum of the van der Waals' radii of hydrogen and chlorine. To carry out reaction (1) we have to perform six times this compression as corresponds to the penetration of the chlorine particles into the spheres of the three hydrogen atoms pointing forwards and the three hydrogen atoms pointing backwards in Fig. 1. The corresponding energy of compression has been calculated.

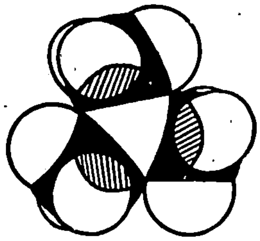


Fig. 1.

The difference between the covalent and van der Waals' radius of an atom is practically the same (0·8 A.) as that between the covalent and negative ion radius. Thus the sum of the covalent radius of carbon and the ionic radius of chlorine will be practically equal to the sum of the van der Waals' radius of carbon and the covalent radius of chlorine. Thus a fair representation of the transition state can be obtained with the Fisher models by setting to each convex side of the central carbon the flat surface of a chlorine atom. (For the central carbon with co-planar valencies a model of the benzene carbon may be used.) This is shown, in the absence of steric hindrance, in Fig. 2, where the chlorine particles *A* and *B* have the covalent radius 0·99 A. and the van der Waals' radius 1·8 A., while the corresponding values for the carbon atom *C* are 0·77 A. and 1·5 A. The distance between the centres *A–C* and *B–C* is the transition state distance 2·3 A.

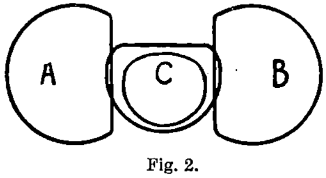

Fig. 2.

By replacing *t*-butyl by *s*-propyl or ethyl, the steric effect is much reduced ; partly by the lessening of the number of points of compression and partly by the possibility of avoiding compression by a bending of the carbon chlorine bonds away from the larger groups. A very considerable steric hindrance can be predicted for the reactions of the neopentyl halides.

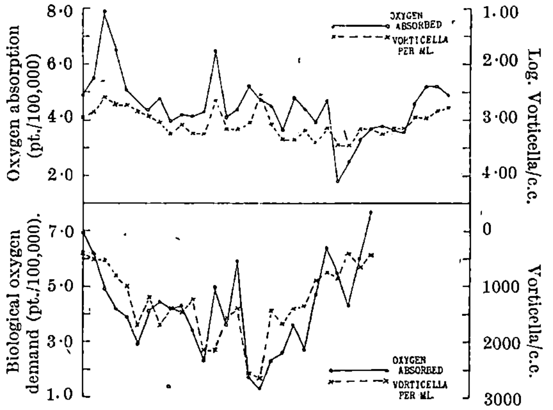
Vorticella as an Indicator Organism for Activated Sludge

It has been recognized for a number of years that the type of protozoan fauna inhabiting activated sludge in a sewage purification plant of this type affords a useful indication of the condition of the sludge. In 1936, Ardern and Lockett[1] stated that they considered this test as the most useful in determining the activity of sludge and listed the common types associated with varying conditions. More recently, Barritt[2] has further enlarged their general findings. It has been concluded that the presence of ciliates and particularly the peritriches to the exclusion of other classes of Protozoa generally indicates a ripe active sludge. But the scope of the utility of this test has been limited by the fact that they were usually qualitative and therefore complementary only to the quantitative chemical analyses.

Preliminary observations of the activated sludge in the plant at Huddersfield indicated that the ciliates were so limited in variety as to afford a simplified case for determining quantitatively the fluctuations in their numbers and in particular of the Vorticella species in relation to the quality of the effluent produced. This limitation in species is probably due to the high percentage of chemical trade wastes in the sewage and is paralleled by a similar limitation of the macro-organisms in the percolating filters[3].

With the exception of Saturday and Sunday, daily counts of the Vorticella species in the channel liquor were made by dilution and centrifuging so that one tenth of a millilitre was fully examined. Correction was made for the variation of activated sludge per unit of channel liquor since the Vorticellæ are only associated with the sludge particles. The chemical analyses were performed daily by other members of the staff. The three-minute oxygen absorption from acidified potassium permanganate and the biological oxygen demand over five days have been chosen as indicators of the quality of the effluent[4].



From preliminary results obtained it was apparent that the condition of the sludge as judged by the chemical analyses fluctuated somewhat irregularly with a frequency occupying three to four weeks. Two typical periods have been examined statistically, the first extending from September 22 to November 7, 1941, and the second from November 28, 1941, to January 1, 1942. During these periods the Vorticella species varied in abundance from 400 to 5,000 per millilitre. The statistical analysis shows that for both periods the degree of correlation between the oxygen absorption test and the Vorticella abundance is very high and negative (first period, $n = 32, r = -0{\cdot}7703$; second period, $n = 23$, $r = -0{\cdot}6925$). A similar result has been obtained for the relation between biological oxygen demand and Vorticella abundance (first period, $n = 25$, $r = -0{\cdot}7661$; second period, $n = 15, r = -0{\cdot}8380$). These correlation coefficients are of such an order as to place almost beyond dispute the relation between the chemical analyses and the biological assay[5].

The results are of importance (1) because they prove that a definite relation exists between the quality of the effluent and the number of Vorticellæ; this is particularly interesting in the case of the biological oxygen demand test since this analysis takes five days to complete; (2) because they show distinct promise for obtaining a more accurate estimation of the condition of the sludge by utilizing a property of the sludge itself and not its product. Furthermore, a method such as this would eliminate the fluctuations in strength and character of the sewage which renders the estimation of sludge condition by the usual chemical analyses often misleading. Vorticella is a particularly useful organism to employ as an indicator since it is easy to identify even by the non-professional biologist, and also their sessile habit renders them easily and quickly counted. After practice the complete estimation can be performed in thirty minutes.

The observations are being continued to discover whether winter cooling of the sewage has any effect on the relation and also to try to establish definite quantitative evaluations for standardizing the quality of the activated sludge. Any active part which Vorticella and other Protozoa take in the purification of sewage remains to be determined.

I wish to acknowledge the assistance of the members of the staff and also the permission of Dr. H. H. Goldthorpe, manager of the Corporation Sewage Works Department, to publish these results.

Rheological Properties of Secretions from the Cervix of Pregnant and Non-pregnant Cows

It has already been observed[1] that the flow-curves for bovine cervical secretions tested in an emptying tube viscometer[2] show a curvature which exhibits cyclic variations closely related to changes in the œstrous cycle. We have since found that, considering only the lower part (first 33 per cent) of the flow-curve, in which elastic fore-effect preponderates, curves plotting log $(L^2 - l^2)$ against log t (which are generally remarkably linear[3]) show greater slopes for cows known to be pregnant (three months or more) than for non-pregnant animals. (L is the initial length of the column and l the length after time t.) The slopes (γ) vary from a value of about $0{\cdot}6$ near œstrus to about $1{\cdot}0$ or a little more at some other point in the cycle and reach values sometimes higher than $2{\cdot}0$ in pregnancy.

Of the first fifty cows tested, twenty-seven were at least three months in pregnancy and all these gave γ greater than $1{\cdot}0$ (normally on the means of two tests). Of the remaining twenty-three non-pregnant animals only one maintained a value of γ greater than $1{\cdot}0$ for more than a day or two. This was a cow which had recently calved and which gave a value of γ greater than $1{\cdot}0$ for about a week, but at the first œstrus, γ fell to a normal value.

Samples of mucus have generally not deteriorated when kept at normal room temperature for about two days, but the technique for preparing them for the test, by homogenization and dilution, requires rather careful control. The values of γ are not seriously affected, however, by quite large changes in viscosity produced by dilution with distilled water, though γ tends to fall with such dilution. The arbitrary choice of pressure of extrusion has little effect, though optimum conditions for such factors make for greater accuracy and reproducibility.

We are investigating the changes which take place in γ during the œstrous cycle and in the earlier stages of pregnancy to establish when γ first begins significantly to exceed the maximum value reached during the œstrous cycle, presumably at the luteal phase. Since the high value of γ might depend on the presence of a corpus luteum and since it is of interest to ascertain whether a high value of γ is diagnostic of early pregnancy (there being at present no satisfactory test applicable to bovines) it is necessary to investigate the behaviour of γ during periods of anœstrus due to retention of the corpus luteum, and this we propose to do.

One of us (A.T.C.) is indebted to the Agricultural Research Council for a grant to undertake these experiments.

Breakdown of Self-Incompatibility by α-Naphthalene Acetamide

SELF-incompatible Petunia, Tagetes, *Trifolium repens* and *Brassica oleracea* have been made self-compatible by spraying the flowering plants with a solution of α-naphthalene acetamide[1]. This new technique has many possibilities to the plant breeder, but without a more complete study of how it works these possibilities cannot be developed properly. Eyster states that "α naphthalene acetamide neutralizes the effects of an ovarian secretion which diffuses into the style and inhibits or greatly retards the growth of pollen tubes". Since there is evidence that incompatibility is due to an immunological reaction between highly specific antigens and antibodies[2,3], it is improbable that α-naphthalene acetamide should be a simple haptene to the incompatibility antibodies of four different genera of plants.

In *Prunus avium*, I find that α-naphthalene acetamide does not increase the rate of incompatible or compatible pollen tube growth, but it does have a profound action on the formation of the abscission layer at the base of the style. Therefore it allows a longer time for the incompatible tubes to reach the ovary. The abscission layer forms two days earlier in untreated and unpollinated or incompatibly pollinated flowers than in flowers treated with α-naphthalene acetamide or pollinated with compatible pollen (see accompanying table). We see, therefore, in this case that the action of the α-naphthalene acetamide is not to 'neutralize' the incompatibility substances but to supply or replace the anti-abscission hormone which is normally produced by compatible pollen tubes or by the ovule immediately after fertilization.

LENGTH OF POLLEN TUBES AFTER FOUR DAYS AND THE NUMBER OF DAYS TO FORM THE ABSCISSION LAYER IN *Prunus avium* VAR. BEDFORD PROLIFIC

Pollen	No treatment		Water		Naphthalene acetamide	
	mm.	days	mm.	days	mm.	days
Crossed *Compatible*	13*	6	13	5	13	7
Selfed *Incompatible*	7·1	4	6·8	3	6·6	6
None	0	4	0	4	0	6

* The 13 mm. incompatible pollinations is an approximation because the tubes at this time were in the ovary.

Since the α-naphthalene acetamide delays abscission for two days, its use may not be confined to removing the bar to self-fertilization but it may decrease inter-specific sterility in plants, especially those with many-seeded fruits. In *Prunus avium*, unlike Petunia, no fruits were obtained after treatment and self-pollination; it is therefore probable that only plants which have a weak incompatibility reaction will be self-fertile after treatment.

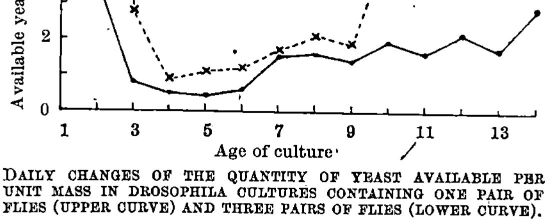
Polygenic Inheritance and the Drosophila Culture

RECENTLY Dr. Mather has directed attention to the importance of the study of polygenic inheritance in relation to practical breeding and to the elaboration of evolutionary theory[1,2]. He has correctly emphasized that failure to study such inheritance lies behind much of biologists' criticism of present-day genetics. However, there is one other important circumstance which, in our opinion, he has not emphasized sufficiently. It is the relation of environment to heredity; the problem of nature and nurture.

In the present context the influence of environment on the expression of heredity has a twofold importance. First, since polygenes "have individual effects which are small compared with non-heritable fluctuations"[2], it follows that their phenotypic expression (or exhibition) is easily modified by environmental changes or differences. Consequently one of the technical difficulties which prevented geneticists from working in this field was the problem of estimating the separate effects of polygenes and environment on the resulting phenotypes. Present statistical methods, as Hogben has pointed out[3], do not always adequately overcome these difficulties. This almost certainly led the "Drosophilists" to concentrate on the study of "unit characters", etc., and to neglect the less easily handled genes or groups of genes the expression of which is easily modified by environment.

Secondly, we have shown that the normal Drosophila culture is not an ideal environment for such studies[4]. As such cultures develop, the *quality* of the yeasts present (the larval food) changes in a more



DAILY CHANGES OF THE QUANTITY OF YEAST AVAILABLE PER UNIT MASS IN DROSOPHILA CULTURES CONTAINING ONE PAIR OF FLIES (UPPER CURVE) AND THREE PAIRS OF FLIES (LOWER CURVE).

or less definite way. This change by itself modifies the phenotypic expression of the variable mutant 'Antennaless'. The *quantity* of yeast available per unit larval mass also changes in these cultures (see graph above). These two major variables will almost certainly affect the exhibition of polygenes. But these environmental changes do not follow the same course in all circumstances[4]. In particular, they are influenced very significantly by the changing numbers of larvæ present in the food medium (see accompanying graph). Hence, in selection experiments care must be taken to ensure that the fertility of females is not altered as selection proceeds. Indeed, Mather's surprising results[1] *may* be explained by such a selection for fertility taking place at the same time as selection for the character studied.

As a corollary to this we may say that the study of polygenic inheritance will be successful only when the technical difficulties outlined above are overcome. As a contribution to their solution we suggest that experiments on selection and inheritance of polygenes in Drosophila be conducted using sterile culture media Such media reduce variability to a considerable degree and permit the handling of constant members of larvæ[4].

Absorption of Minimal Doses of β-Carotene by Vitamin A-Deficient Rats

Wide differences between the theoretically expected and experimentally obtained potencies of pure vitamin A as compared with β-carotene have led to a considerable amount of speculation[1,2] on the possible manner of conversion of carotene into vitamin A *in vivo*. While there is no direct evidence in support of the postulated unsymmetrical fission of the provitamins, we felt that it might be of interest to study the extent of absorption of β-carotene by rats under the conditions of biological assay.

In the course of these experiments, it was observed that analysis of the fæces of rats maintained on a carotenoid-free diet gives an apparent carotene excretion value of 0·2–0·4 μgm. per rat per day. Examination in a visual spectrophotometer showed this to be due to a non-carotene pigment possessing only a general absorption. By chromatographic adsorption analysis on columns of Brockman's alumina it was possible to separate the carotene from the associated impurity and estimate it quantitatively. The identity of the excreted carotene and the non-carotene nature of the other pigment were confirmed by spectrophotometric data and growth experiments on rats.

Coconut oil content of diet (per cent)	Level of dosage μgm. β-carotene per rat per day	Amount of β-carotene ingested (μgm.)	Apparent carotene excretion (μgm.)	On separation			β-carotene excretion (per cent)
				Non-carotene (μgm. equiv.)	β-carotene found (μgm.)	β-carotene calculated (μgm.)*	
3	1	224·5	114·9	27·3	28·7	31·9	14·0
,,	2	448·9	159·0	40·4	49·8	55·3	12·3
10	1	204·0	117·0	36·0	22·8	25·3	12·6
,,	2	544·0	190·5	59·4	59·5	66·1	12·0

* Chromatographic analysis of known mixtures has shown the caroene recovery to be about 90 per cent, and these values are calculated on this basis.

Some experimental results are summarized in the accompanying table.

The figures presented in this table represent the total amounts for each group of 6–7 rats over an experimental period of 5–6 weeks.

It should be mentioned, however, that in order to get sufficient quantities of the pigments, it was necessary to collect the fæces of each group of rats for 10–14 days and preserve the same in the refrigerator before analysis could be performed. During this interval, a part of the carotene might have undergone destruction and therefore it is probable that the actual excretions were considerably higher than these figures would indicate.

In contrast to the behaviour of carotene, which may be due to its hydrocarbon nature, vitamin A is known to be quantitatively absorbed at far higher levels of intake; at any rate, no excretion could be detected[3,4]. It is therefore suggested that the incomplete absorption of β-carotene might be the major factor responsible for the observed discrepancies; after absorption, perhaps β-carotene is as efficient as vitamin A at the levels of the biological assay.

In a note[5] which reached us during the final stages of this investigation, Wald *et al.* arrive at a similar conclusion based on the results of absorption studies on human subjects at higher levels of intake.

Further work is in progress and full details will be published elsewhere.

Chemical Composition of Mitochondria

In 1908 Regaud[1] suggested that mitochondria were "*corps lipoïdes*", and the following year[2] he pointed out the general resemblance between the myelin of nerve fibres and the substance of mitochondria in their reactions to histological fixation and staining. The theory that mitochondria contain a relatively large amount of lipines held its ground for a quarter of a century.

In 1934 Bensley and Hoerr[3] succeeded in actually separating the mitochondria of the liver of the cavy from the rest of the cell, and produced cakes of nearly pure mitochondrial substance in considerable quantity. Roughly a third of this substance is soluble in fat-solvents[4], and it was naturally anticipated that a large proportion of this would consist of lipines. On the addition of acetone, however, a very small precipitate was formed, and it was concluded that only about 4 per cent of the material of mitochondria consists of lipines, the rest of the fatty material being true fat.

Bensley's conclusions differ so widely from those of previous students of the same subject that one looks for a possibility of reconciliation. May it not be that lipines are present in the ether-soluble fraction of mitochondrial substance in considerable amount, but largely resist precipitation by acetone? Ciaccio[5] has especially stressed the solubility of lipines in acetone when other fatty or fat-soluble substances are also present, and Kaufmann and Lehmann[6] have shown that if 2·1 gm. of oleic acid be added to 45 c.c. of acetone covering 2 gm. of lecithin, about half the lecithin goes into solution.

It would be most helpful if those who are expert in the technique of isolating mitochondrial material in quantity from cavy liver could be persuaded to apply tests for lipines to the large fraction of fatty material that is not precipitated by acetone.

Reversible Quenching by Oxygen of the Fluorescence of Polycyclic Hydrocarbons

We regret that, as Dr. E. J. Bowen has pointed out[1], the important paper of Bowen and Williams[2] on the photo-oxidation of aromatic hydrocarbons has indeed escaped our notice, but we hope that our previous communication[3] has served a useful purpose in directing attention to the occurrence of the phenomenon in the visible fluorescence of cancerogenic hydrocarbons where it has not hitherto been described. This reaction is not only of practical importance for analytical fluorescence measurements, but also of theoretical interest as a possible initial stage in the metabolic oxidation of these substances.

Determination of Water in Soils

The usual method for determination of water in soils (that is, heating to 110° C.) is almost always unsatisfactory owing to decomposition and slow oxidation of organic matter; moreover the determination takes a long time to complete.

A series of experiments have therefore been carried out using the method described by Lowndes[1], using a Dean and Stark's tube. The sample is thus distilled under xylene or toluene (b.p. 137° and 110·7°), the water which comes over being weighed or its volume read off. The determination is completed in 2–4 hours and losses due to oxidation are avoided.

It will be seen that the results for a well-cultivated loamy garden soil are consistent among themselves and that the results with toluene agree with those obtained with xylene. With samples of chalk it was possible to apply a check by oven-drying, showing that the method is working satisfactorily.

Results with a dark clay loam

Sample	Appt. no.	Liquid used	Water (% dry wt.)	Average %
IV	3	Xylene	8·5	8·3
	6	,,	8·3	
	5	,,	8·0	
VIII	3	Xylene	21·2	21·2 (with xylene)
	6	,,	21·2	
	8	Toluene	21·7	21·8 (with toluene)
	4	,,	21·9	
I, *a*	9	Xylene	33·5	33·6
	5	,,	33·8	
	3	,,	33·6	
V	3	Xylene	56·3	55·8 (with xylene)
	6	,,	55·3	
	8	Toluene	56·4	55·9 (with toluene)
	5	,,	55·3	

Results with chalk (using xylene)

Appt. no.	Water (% dry wt.)	% water (by oven drying at 110°)
1	23·8	24·8
2	23·5	24·4
2	22·2	22·4
2	13·2	13·5
3	7·2	7·0

These results have not been corrected for the small amount of water left on the walls of the apparatus, which amounts to about 0·1 gm. but varies with the construction of the tube.

Further work is in progress on the application of this method to the investigation of soil moisture, but as there seems to be no doubt of its suitability and obvious advantages for most purposes, it was felt that the above preliminary results were worth putting on record.

Molecular Sodium Hydride in Interstellar Space

In a recent article[1] describing results obtained with the coudé spectrograph of the Mount Wilson Observatory, W. S. Adams gives some details of the identification of a number of interstellar lines with absorption lines of various molecules in their lowest possible energy states. Among others he mentions a line at λ 3934·3 provisionally assigned to NaH by McKellar[2].

Now the hydrides of the alkali metals are characterized by spectra containing band systems of rather unusual intensity distribution. For the molecule RbH an approximate calculation of the relative intensities of the bands of the system in emission has been made by Gaydon and Pearse[3]. The results may be applied to absorption by molecules in the lowest state by assuming an initial distribution of all the molecules in the level of the lower electronic state for which $v'' = 0$, instead of a Maxwell distribution among the vibrational levels of the upper electronic state. The factor ν^4 is also changed to ν for absorption, but this is relatively unimportant in its effect on the results. This has been done in the course of an investigation of the spectrum of the NaH molecule by R. C. Pankhurst with the results shown in the accompanying table.

v',v''	λ	I_0	I_c
0,0	—	—	0
1,0	—	—	0
2,0	—	—	0
3,0	—	—	1
4,0	4230·6	0	3
5,0	4169·0	2	7
6,0	4108·4	5	16
7,0	4049·0	7	27
8,0	3990·9	9	42
9,0	3934·3	10	50
10,0	3879·4	10	50
11,0	3826·0	9	—
12,0	3774·3	9	—
13,0	3724·5	9	—

Here v',v'' are the vibrational quantum numbers of the upper and lower levels, λ is the wave-length given by Hori[4] for the R (0) line of the band as observed in absorption, I_0 is his corresponding band intensity, while I_c is the value of the intensity obtained by calculation. It will be noticed that the experimental and calculated values agree on the general course of the intensity from vanishingly small values near the origin of the system rising steadily to a flat maximum in the (v', 0) progression. Without laying too much stress on the actual numerical values, which are based on an arbitrary scale of 50 for the maximum in the calculated relative intensities, I_c, and are eye-estimates on a scale of 10 for the maximum in I_0, it may be noted in favour of the assignment that the transition observed, namely (9,0), is in the region of the maximum, but since in this region the intensities of neighbouring bands are so nearly the same, it would seem that they also should be obtained. If this could be done the probability of the identification being correct would be greatly strengthened.

Reflexion from Paper

I have observed a curious optical effect which I have not seen described anywhere. If an open book is illuminated fairly strongly from one side, for example, from over one shoulder, the general colour of the white paper is different for the two eyes when one or the other is closed. The effect has been tried with several subjects with the same result. When the light comes over the left shoulder and the left eye is open the pages have a bluish tinge; when the right eye is open and the left closed the tinge is reddish. If the light comes over the right shoulder the above effects are reversed. If the light is centrally placed above and behind the head there is no difference.

E. Burke.

5 Watts Avenue,
Rochester,
Kent.

I think the effect Mr. Burke describes is due to selective specular reflexion from the paper. Many near-white papers are slightly more glossy in red light than they are in blue; that is, the specularly reflected light contains relatively more red and less blue than does the incident light. If the incident light comes over the left shoulder, the right eye will be rather nearer the angle of specular reflexion than the left, consequently the light reaching the right eye will be a little richer in red.

The effect can be observed in more pronounced form with many glossy coated ('art') papers, if they are illuminated and viewed at an angle of about 70° to the normal: the diffuse image of the light source appears distinctly orange or reddish compared with the source itself.

History of the British Thermal Unit

The date of the phrase "British thermal unit" can be pushed back by fifteen years; it occurs in W. J. M. Rankine, "Manual of the Steam Engine" (1859), p. 300; but here, as in the 1875 quotation given by Dr. Powell[1], it is a descriptive phrase and not a technical term; Rankine is in fact contrasting the British thermal unit and the French thermal unit.

It occurs, however, as a technical term in 1889 in De V. Wood, "Thermodynamics", 3rd ed. (New York), p. 3 ("The British Thermal Unit (B.T.U.)"). (I have not been able to consult earlier editions of this book.) H. Evers, "Steam" (1889), p. 4, speaks simply of "A Unit of Heat"; M. H. Wright, "Heat" (1893), p. 79, says: "In England the unit of heat or thermal unit is . . ."; W. S. Hutton, "Steam-boiler Construction" (1891), p. 4, speaks of "The British thermal unit".

It would seem likely that it was in the United States that it was first found necessary to incorporate the word British in the name of the unit, and that the phrase then recrossed the Atlantic as a technical term, and reached British physicists by way of British engineers.

POST-WAR PLANNING IN RADIO TELECOMMUNICATION

THE meeting of the Wireless Section of the Institution of Electrical Engineers on May 6 was devoted to a discussion on "Post-War Planning in Radio Telecommunication", which was opened by Sir Stanley Angwin, engineer-in-chief of the Post Office, and a member of the committee of the Institution studying the possibilities of post-war planning in electrical engineering in general. While it is true to remark that all possible efforts on the part of radio engineers and physicists should be devoted to ensuring that the present conflict will lead to a victorious issue for the Allies, it is equally wise to observe that those with experience and responsibility should divert a little of their time to the consideration of the problems which will most certainly arise at the termination of the War.

Sir Stanley's opening remarks were concerned chiefly with the probable developments in post-war telecommunications—line, cable and radio—for conducting the normal peace-time business of the world, while, in addition, he outlined the probable future of broadcasting, television and the application of radio technique to various spheres, in particular, navigation. It is already clear that radio telegraphy and telephony on one hand, and the submarine cable and land line on the other, are complementary services, and their respective applications are decided by matters of distance and geography, as well as by technical considerations. In both this field and the similarly extensive field of broadcasting, it will be necessary after the War to resume consideration, on a world-wide basis, of the equitable division of radio frequency channels among the various services requiring them. The putting into effect of the most recent plan for the distribution of the frequencies or wave-lengths of European broadcasting stations, was interrupted by the outbreak of war; but in any event a considerable revision of this plan will probably be necessary on a return to normal conditions.

The design and development of broadcasting transmitters and receivers will need to be reviewed in the light of advances of technique and knowledge, and a certain amount of standardization may become necessary. In the field of television the technique of the service, and in particular the mode of presentation of the picture in the receiver, must be reviewed in some detail. With the view of relieving the radio channels of all unnecessary traffic, it is likely that more serious attention will be required to the scope offered by the use of land-lines for the distribution and relaying of broadcasting and television programmes. Finally, Sir Stanley Angwin referred to the problems which will have to be faced in connexion with the return to industry of staffs at present in the Services or in Government establishments. The radio and telecommunications industry will also have to deal with the technical matters connected with the reopening of overseas markets, if we are to take a proper position in world trade.

In continuation of the discussion, Dr. R. L. Smith-Rose referred to various problems likely to be encountered in connexion with fundamental research and development, the technical standardization of equipment and components, the re-allocation of personnel at present engaged on radio work, to the recognition of the radio-physicist as well as the properly qualified radio electrical engineer, and finally to the matter of post-war publication.

In the field of research, it will be found that whi the radio wave spectrum has been considerabl extended during the War, much of the ground w have been hurriedly and only very superficial explored, and there will remain a good deal of wor in the examination and consolidation of principl and technique before it will be possible to make th best use of the frequency bands then available. will probably be found necessary to extend the rang of research, both fundamental and applied, in orde to find room and allocations for the greatly increase number of services which will be awaiting applic tion. In connexion with this matter, it will be nece sary to give renewed attention to the technic merits of wired broadcasting, single side-ban transmission, and the possibilities of the very sho wave bands for relays and short-distance radio link With the extended use of the very short wave-length the subject of interference and its suppression will b brought into the limelight again, particularly a many of the purposes to which radio technique ha been applied during the War are not conducive t freedom from interference.

If the radio industry is to develop satisfactorily o an extended basis at the end of hostilities, it i likely that a considerable amount of standardizatio of valves, components and equipment will be neces sary, while there will be ample work for those whos duties include the preparation of specifications an test schedules. In the latter connexion, it will b desirable at a very early stage to lay down a state ment or code of safety precautions to be followed i dealing with the very high voltages found nowaday in radio receivers and cathode ray tube apparatus During present conditions much of this gear ha been produced hurriedly, and without the precau tions which have hitherto been considered essentia by the fully trained and experienced electrica engineer.

With regard to the question of personnel an staffs, Dr. Smith-Rose believes that while many a present attracted to radio work in the variou Services will return to their different peace-tim occupations, many—especially the younger member —will attempt to stay to make a career in som branch of the radio industry. This influx of per sonnel will present a problem for the Institution o Electrical Engineers itself to deal with, for whil many of these radio workers will possess adequat academic qualifications in science, and some practica experience, they can scarcely be classed as full qualified electrical engineers according to the Insti tution's standards. Furthermore, many of thos who return to their normal occupations in science art or business are likely to wish to retain an interes in radio as a hobby, and the Post Office authoritie might well be thinking over their future attitud towards the post-war radio amateur. The universitie will also have to recognize a continuous need fo properly educated recruits to a stable and growin profession, and it will be clearly desirable that well-arranged graduate course in communicatio engineering should rank on an equal footing in th future with electrical engineering.

Another matter that may well receive consideration in advance by institutions and societies, as wel as by the technical periodical Press, concerns th method of handling the vast volume of publication that will suddenly become available when the existing barriers of secrecy are removed. Indeed the quantity of radio literature that will pour out under post-war conditions may demand a considerable extension in our present methods of systematic arrangement, abstracting and indexing. In this connexion, two useful suggestions were made later in the discussion, by Mr. D. A. Bell and Dr. L. E. C. Hughes. The first was to the effect that it would prove very desirable to institute some kind of critical reports of progress in the various phases of radio technique, perhaps on the lines of the series of annual reports already issued by the Physical Society; while the second directed attention to the desirability, if not of the necessity, of using micro-film technique for the recording of published papers.

Messrs. V. Z. de Ferranti and C. E. Strong outlined the difficulties which are likely to confront a radio industry suddenly called upon to make a change-over from the carrying out of war contracts to Service specifications, to the re-establishment of a peace-time industry on a stable basis. It is clear that the present radio industry has not been planned on a sufficiently large scale, and it was suggested that this experience should be borne in mind in the future. At the termination of the present War, it is probable that the whole radio industry will require an interval in its production programme while the design and development of the new peace-time equipment is carried out. Some considerable foresight will be needed here to retain groups of staff and workers intact over a comparatively slack period before the industrial machine gets into its new stride.

Mr. J. A. Smale said that he anticipated many developments in the field of point-to-point radio telegraphic communications, including the use of printing telegraphs and coded messages. To a large extent the standards of transmission have been relaxed during the War, and it will be necessary to recover these if all the available channels are to be used in the most efficient manner. Mr. A. D. Blumlein expressed the somewhat comforting opinion that the methods of distributing television programmes used in 1939 were about right, and, apart from minor improvements, would need only slight revision to resume broadcast operation.

The probable directions in which the broadcast receiver industry is likely to resume activities were examined in some detail by Dr. R. C. G. Williams, who believes there is the possibility of some Government control of the industry as an outcome of a reconsideration of the political side of broadcasting. Both he and other speakers envisage the possibility of the use of an improved projection type of cathode ray tube for obtaining better picture reproduction in domestic receiving equipment.

After further contributions by other speakers, the discussion was brought to a close by Mr. H. Bishop, chairman of the Wireless Section of the Institution. It is desirable, he said, to plan a bold policy of expansion in the whole field of telecommunications, and this will of necessity involve dealing on a national basis with all the problems which have been brought forward, and particularly those of staff, education, and research and development. He referred to the difference in standards in television in the United States and in Great Britain, and agreed that our own system could quickly be ready for the resumption of a satisfactory public service. He also referred to the desirability of encouraging increased co-ordination in the field of post-war research, and expressed the hope that many secret devices developed under war conditions will be released for a peace-time application in due course for commercial purposes.

THE FUTURE OF TECHNICAL EDUCATION[*]

By H. J. CULL

IN common with all sections of the community, technical teachers find the progress of the War marked by increasing demands upon them. Apart from special courses, the average experience appears to be of a large increase in the part-time day classes of the colleges and the maintenance of evening or the substituted week-end classes at something approaching their normal level. To cater for these with, in many cases, depleted staffs has called for sacrifices of many of our cherished ideas as to conditions of service—changes in hours of duty per week, sizes of classes and suitability of accommodation for classes—which will demand the watchful care of the Association if they are to be regarded as temporary expedients and not precedents.

Education and the Future

Prominent in our thoughts in spite of many preoccupations is the discussion which has been in progress during the year on educational post-war reconstruction. Inspired in the first place by an official invitation by the Board of Education, the executive of the Association of Teachers in Technical Institutions, as well as similar groups within other major educational associations, has given consideration to this matter. Official pronouncements by succeeding presidents of the Board of Education, as well as provisions already on the statute book awaiting the announcement of "appointed dates" and also the war-time developments of activities among young people, make certain steps in reconstruction almost self-evident. It would appear, for example, that after the age of eleven plus, all schools should be secondary in character, equal in status, and administered by one department of the Board of Education. The main interest here of the Association is to secure the continuance as individual entities of those schools which have so fully justified themselves during recent years, namely, the junior technical schools. These schools, giving a broad general education; with a scientific approach to an industry as a whole; working in close association with the industry of the district; and provided with the equipment and the qualified staff to give the industrial bias, have achieved a success which cannot be questioned. The one handicap which has always been present and has had to be overcome has been the suggestion of inferiority due to the later age of entry when compared with other types of schools. If this be removed by the general reconstruction, we have no fear that the schools will produce youths who will be other than a credit to themselves and any society in which they are partners. Pioneers in this type of school are convinced of their value from the point of view of the student—not alone of the industry which they join. The realistic approach to the studies means much to certain types of young people, and that is the real justification for wanting to preserve the schools and extend the experiment.

We are watching a development of adolescent education in two distinct directions at the moment. Firms are releasing for part-time day education employees in larger numbers than ever before.

---

[*] Substance of the presidential address delivered before the Association of Teachers in Technical Institutions on May 23.

Tribute must be paid to those firms who have thus met the difficulties of the youths in continuing their technical studies. It is believed that this war-time experience will persuade many firms of the value of this education, to their employees and to themselves, and that it will grow on a voluntary basis from year to year. Nevertheless we feel that part-time release should be made obligatory from the statutory age for full-time education, up to the age of eighteen. Much of such part-time work would be vocational in character and would be centred around the technical college.

Youth service is being officially sponsored in Great Britain for the first time. If part-time release for educational work is part of the reconstruction scheme, there must grow up in most districts a new type of school, already tried in a few areas, namely, the day continuation schools. This new youth service would in many cases seem to fuse with the work of the day continuation school. At the moment, the youth activity is bound to be war-biased, but one can hope that the aim of the combined day continuation school and youth activity will be to develop that complete personality inherent in us all—involving physical well-being; a developed mind able to appreciate and express; and a spiritual entity able to appreciate beauty in many directions and to take part in its perpetuation. So we find a further problem facing us on the technical side. Our organization of the vocational needs must be such as will not debar the youth of our colleges from a goodly share in physical and humanitarian activities.

Full-time Technical Education

In general reconstruction, too, the technical teachers would expect to realize some of those projects for which they have pressed for many years. For example, technical colleges have a contribution to make to a developing society by a more widely developed system of full-time courses. These might be attended by students coming direct from other types of schools, but perhaps more frequently by suitable partly trained students securing release from industry for a period to complete a course of training. Many pronouncements are made in these days that university students benefit greatly if they preface their university studies by some period in employment. This would probably be even more true of full-time work in technical colleges. Associated with this is the whole question of scholarships for these senior students in the colleges, which we have claimed as deserving of official attention for some years now. Regional co-ordination of the senior colleges is a further point which will need consideration in the complete scheme.

As we plan now for a post-war community we are largely groping in the dark. We do not know much of the conditions in which we shall find ourselves. For this reason we should refrain from being closely fettered by decisions. We believe victory will bring us a greater measure of freedom to develop as individuals and as members of an international commonwealth. The great aim should be that we as teachers shall be ready to seize our opportunities on behalf of the youth of the country and bring to them better fruition than ever before. Led by a president of the Board of Education of full cabinet rank and able to make demands as a right to a full share of the country's resources for education, we should be alive to every possibility of advance along the lines we have set. Perfect buildings, staffs large enough and well enough trained for the perfect schools, equipment worthy of the standard set will probably be acquired only slowly. But war-time training of youths has produced results which have not reflected the difficulties under which it has been carried out. Under peace conditions we need not wait for the perfect surroundings before starting to train youth to make the most of their personalities.

Building and Agriculture

Turning to more immediate problems, we find evidence of much that demands careful thought. The Board of Education has indicated the need for the development of junior technical schools for the building industry. No departments of our colleges have suffered more in the depletion of their work during war-time than those of building. Yet imagination does not need much scope to see the immediate importance of this industry after the War. The Association welcomes the suggested encouragement of these schools. It visualizes them as being schools of the type mentioned previously, presenting an approach-view of the industry as a whole. Such a training would lead to a definite apprenticeship and form part of the apprenticeship training. There is time to plan this as a complete scheme and a permanent one, and it should not develop as a rough preparation for immediate post-war needs only. The industry and the senior college building departments must be important partners in the plan.

Another aspect of technical education has been recently considered: that affecting agriculture. Though of course provided with its own unique difficulties, the needs of this industry for a scientific background to its studies is as great as any other.

SCIENCE AND THE WAR EFFORT

A "SCIENCE for Victory" Conference, organized by the Southern Area Committee of the Association of Scientific Workers, was held at University College, Southampton, on May 17. The meeting attracted scientific and technical workers from a wide area of southern England. Mr. Alexander Orba (instructor in radio at University College) presided at the afternoon session, and opened the Conference; he said that this was the first representative gathering of scientific and technical workers to be held in the Southampton area, to discuss the organization of their affairs and represented an important step forward in the part to be played by scientific men in the life of such an industrial area.

The opening speaker was Mr. H. W. Steele-Bodger, past president of the National Veterinary Medical Association, who spoke of the part veterinary science can play in the war effort by increasing the production of such foodstuffs as meat and milk. He emphasized that agriculture is really the basic and fundamental science and must be kept alive and flourishing if the people are to be fed. A Survey Committee of the National Veterinary Medical Association produced a comprehensive scheme for the control of diseases of livestock, and after years of patient effort had persuaded the Ministry of Agriculture to adopt it. As a result, he was confident that milk production would be very materially increased by the winter of 1943. In general, however, such progress is hampered by ignorance of veterinary science, even in the highset quarters, and by conservatism and lack of co-operation among the farming community.

Mr. C. F. Carr, editor of the *Southern Daily Echo*, gave a short talk on "Science and the Press", in which he expressed the view that unless the newspaper industry is prepared to encourage research directed towards speeding up and improving its own productive processes, it will soon be completely out-done by broadcasting. He hoped they would get down to this and also that the Press might be to a much greater extent the vehicle for disseminating scientific knowledge to the public.

Dr. Harry Barron, head of the Plastics Department of Pirelli-General Cable Works Ltd., spoke on the subject of synthetic rubber. He explained how vital rubber is, not only to the war machine, but also to industry as a whole; no longer can oil and steel be regarded as the only criteria of a nation's ability to make war. Since the loss of natural rubber supplies in the Far East, Great Britain may have difficulty in lasting out this year on existing stocks. The U.S.S.R. and Germany both built synthetic rubber industries years ago; the United States started some time ago to build up such an industry; but in Great Britain, owing to the continual obstruction of powerful vested interests, no start has been made even now. Not even the essential raw material—carbide—is available, as we have no carbide industry. The American industry will not be in a position for a year or two to supply us with quantities large enough; 50,000 tons a year has been glibly talked about, but the total production this year is unlikely to exceed 40,000 tons. We need to be most economical in the use of rubber, and to save every scrap for reclamation. Dr. Barron thought we should set about solving the problem immediately by building quite small pilot plants, in order to gain experience in the processes and to train the technicians needed.

The evening session was presided over by Dr. Barron, who read out a letter from the Association of Scientific Workers to branches in the radio and electrical industries, asking for information about the misuse, wastage or under-employment of technical resources, about which a Committee of the War Cabinet has asked for investigations to be made.

The first speaker was Mr. C. E. G. Bailey, of the Mullard Radio Valve Co. He spoke on "Radio Research and the War", and began by describing the peace-time condition of the industry, in which, except for television development carried on almost exclusively by the large firms, technicians were mostly engaged in thinking out sales points, such as fancy tuning scales and push-button circuits. Little real research was done. At the same time, the few Government establishments maintained were hampered by inter-Services rivalry and by the difficulty of obtaining the best scientific brains, owing to humdrum conditions of work. The crisis of war has made plain the need—previously seen only vaguely—for the industry to change from the spirit of commercial competition to one of technical co-operation if real progress is to be made. Even at this eleventh hour, co-operation between the Services, between firms and between Services and firms, and the proper allocation of jobs, are only just being organized on a reasonable scale.

Turning to the subject of post-war reconstruction, Mr. Bailey said that this is a two-edged term. It is usually interpreted by employers as meaning that they must carve a niche for themselves in the post-war markets, so as to "avoid dismissing their employees". However, we must not employ technicians now in designing broadcast receivers on the old competitive lines, when their services are so vitally needed for war work.

In the subsequent discussion, one speaker suggested that the Association of Scientific Workers should be ready to put forward a general plan for the post-war industry, which would indicate future lines of research and ensure that ample work is available.

The final contribution was by Mr. Alexandra Orba, of University College, Southampton, on "Technical Education". He outlined a plan for education designed to produce the technicians required for immediate war-time needs as rapidly and efficiently as possible, and at the same time to lay the foundation for a more satisfactory educational system after the War. We shall then have a larger number of people with technical knowledge than ever before, and we must take full advantage of this to build up a different attitude towards science and its cultural value. We must see that the vocational training given is related to the needs of society at the time and the estimated future needs; we must train staffs for all grades of work in industry, for executive and administrative posts as well as technical ones.

There was considerable discussion following this address, and a resolution "That the Board of Education be urged to give consideration to the need for teaching all school children something of the organization and processes of modern industry" was carried.

The Conference served a useful purpose in focusing attention in the area on the need for the application of scientific effort both immediately and for the future, and a number of resolutions arising out of the papers which had been discussed were passed.

LONDON SCIENTIFIC FILM SOCIETY

THE London Scientific Film Society gave a demonstration of films on May 16 at the Imperial Institute cinema. Dr. Julian Huxley introduced the film "Galapagos" and led a discussion on it afterwards. The film was made by the Dartington Hall Film Unit under the direction of Mr. William Hunter and Mr. David Lack and was photographed by Mr. Richard Leacock. It illustrates the comparatively free adaptive evolution of new types, in absence of competition, from original single colonizations on a group of oceanic islands. The extent of the differences from the mainland forms depends on the time that elapses since the colonization. In such cases, where the pressure of natural selection is light, the animals are not as well equipped to fill their environmental niches as are mainland forms. For example, there is a member of the gull tribe, the close ancestors of which are water birds, which nests in the trees although it still retains webbed feet; and the finches have evolved a range of species to exploit the available food supplies, although the shape of their beak, unlike those of most mainland birds, does not always give a precise indication of the food habits of the bird.

Dr. Huxley also pointed out that there is a tendency to gigantism in absence of competitors, as shown on the Galapagos by the giant tortoises and iguanas, and that animals can extend to unusual habitats, as shown here by the unique sea lizard and the red land crabs.

The film is well photographed, but it is to be regretted that there are no pictures of the mainland birds from which the island forms evolved and that the captions are scarcely sufficient to explain the purpose of the film. It was pointed out that the absence of sufficient funds explained some of the unavoidable deficiencies of the film and why it was only available on 16 mm. silent film.

In the discussion which followed it was asked whether any steps are being taken to preserve such valuable films, which show animals that are fast becoming extinct. It was explained that the National Film Library of the British Film Institute has as one of its aims the preservation of films which illustrate the development of the cinema and of social history, but that it does not collect films specially for their scientific or technical content. The Scientific Films Committee of the Association of Scientific Workers (on whose recommendations the programmes of the London Scientific Film Society are largely made) has recently made a plea to the National Film Library for the preservation of scientific films and has made out a list of those that it considers should be obtained now. "Galapagos" is one of them.

Other films shown by the Society at this meeting were: "Propeller Making", "This is Colour" (an Imperial Chemical Industries film in Technicolor about dyes), "A Few Ounces a Day" and an excellent film epic recently arrived from the United States of the building of the Boulder Dam in Colorado.

FORTHCOMING EVENTS

Saturday, May 30

Nutrition Society (at the London School of Hygiene and Tropical Medicine, Keppel Street, London, W.C.1), at 11 a.m.—Conference on "Problems of Collective Feeding in War-time".

Monday, June 1

Royal Geographical Society (at Kensington Gore, London, S.W.7), at 5 p.m.—Geographical Films.

Friday, June 5

Geologists' Association (in the Rooms of the Geological Society of London, Burlington House, Piccadilly, London, W.1), at 5.30 p.m.—Prof. Frank Debenham: "Shelly Drift in the Antarctic".

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Head of Department of the Junior Technical School for Building in the Bournemouth Municipal College—The Director of Education, Town Hall, Bournemouth (June 4).

Lectureship in Clinical Pathology—The Secretary, University College, Cork (June 6).

University Chair of Biochemistry tenable at St. Thomas's Hospital Medical School—The Academic Registrar, University of London, Richmond College, Richmond, Surrey (June 8).

Lecturer in Pharmaceutical Subjects—The Principal, Leicester College of Technology and Commerce, The Newarke, Leicester (June 13).

Assistant Mistress to teach Biology and Subsidiary Chemistry—The Clerk to the Governors, South-East Essex Technical College, Longbridge Road, Dagenham (June 13).

Chemist to assist in an investigation on the production of organic fertilisers—Prof. H. A. D. Neville, The University, Reading.

Mechanical Engineer for Mine on the Gold Coast engaged on production of essential war material—The Secretary, Ministry of Labour and National Service, Central Register (Ref. O.M.C. 968), Public Trustee Office, Sardinia Street, Kingsway, London, W.C.2.

LEADERSHIP FOR THE NEW ORDER

AT a time like the present, when the war effort is rising steadily towards its maximum and fighting has intensified, there is apt to be impatience when the call for consideration of reconstruction and the future of the world is raised. Thus at the Labour conference held during Whitsuntide, criticism was directed against Labour Ministers for failing to secure more vigorous prosecution of the War, whereas long-range policy was given a subsidiary place. Nevertheless, even in the stress and turmoil of a world struggle, the foundations on which a better world shall be erected must be established ; even although it is neither possible, nor perhaps desirable, to particularize, there should be some clearer conception of the future state of society in the minds of leaders of thought than is apparent among the general public. It is the task of those who have thought about what is to follow the end of the War to prepare the minds of others. Two notable recent speeches by Mr. Anthony Eden, Secretary of State for Foreign Affairs in Great Britain, and Mr. Henry A. Wallace, Vice-President of the United States, respectively, have given valuable leads.

Mr. Eden was speaking at Edinburgh on May 8, and devoted a portion of his address to the post-war world. He emphasized that, speaking as Foreign Secretary, he had in mind particularly the problem of keeping the peace. Without peace there is nothing for the future but ever-increasing social stress ; and peace does not mean merely the absence of war. Peace in the true sense means stability in international relationships and active co-operation between all peoples ; it is an affair for long years of effort, determination and good will. A peace treaty, however skilfully and thoroughly discussed, is but the skeleton, which can only be clothed with flesh and blood by human will and perseverance. The War has demanded intense effort and sacrifice, and we must not grudge similar sacrifices for peace. Every country has a direct responsibility for maintaining the peace. The increase in speed of communication characteristic of the pre-war period has been intensified by war conditions, so that in effect the world is shrinking, and the good-neighbour policy is becoming more and more important for the future of mankind.

But just as social advancement is conditioned by peace, so is peace dependent on improvement in social conditions. Unemployment, malnutrition and low standards of life, in any country whatever, are each capable of endangering world peace. The British Commonwealth of Nations, the United States of America, the U.S.S.R. and China must therefore assume responsibility for the economic reconstruction of the world. This may mean economic sacrifices on the part of individual nations, but they will be well worth while if they can avert another world catastrophe. On a smaller scale, similar problems in connexion with the Colonial Empire will confront Great Britain ; again the answer will be sacrifice, for the greater good of the many.

Mr. Eden's speech followed closely on the heels of addresses by Sir Stafford Cripps and Mr. Oliver Lyttelton, who also stressed the needs of the post-war world. Taken together, they are an encouraging sign that members of the Government in Great Britain not only appreciate some of the difficulties which lie ahead, but also the need for bold leadership in attacking them.

Mr. Henry Wallace was speaking on May 21 to the Free World Association, and, as the 'second man' in the United States, his words obviously were intended to convey the views of the United States Government. His speech emphasized in the first place four duties—again the stress was on giving rather than receiving. Referring back to the now well-known "four freedoms" enunciated by President Roosevelt in January 1941, he said they constituted nothing less than a people's revolution, towards the accomplishment of which the present time demands four duties: to produce to the limit, to transport as rapidly as possible to the field of battle, to fight "with all that is in us", and to build a just, charitable and enduring peace. This last inspires the other three duties. Modern science, he said, is "a by-product and an essential part of the people's revolution", and by its aid it is possible to ensure that everyone has enough food. Sufficiency of food is the first requirement in raising the standard of living, which is itself an essential part of the peace which must follow this War and must embrace not only the United Nations but also the Axis Powers. Scientific developments and their applications are thus, on Mr. Wallace's showing, an integral part in the advancement of society. "Modern science, when devoted wholeheartedly to the general welfare, has in it potentialities of which we do not yet dream."

As regards the part that America will play in the future ordering of world affairs, Mr. Wallace was very emphatic that it will continue the active collaboration of which the War has seen the beginning. It may even have the privilege, he said, of suggesting the freedoms and duties of the "common man". The motive will again be service, the older nations helping to start the younger nations along the path of industrialization. Productivity must be increased, so that the "common man" and his children may repay the world community all they have received. World peace will have no place for a dominant or master race, based on Nazi or any other ideology, and with that myth must go the old conception of international cartels. Such cartels must be controlled internationally in the interests of the common man, as well as by their home Governments. Invention will thus be made to serve the many instead of the few.

These words of Mr. Wallace will be heartening to those who are striving to look beyond the immediate future. But they also demonstrate the need for fearless leadership in combating the wave of conservatism which is almost certain to come with the release of strain following upon the cessation of hostilities. Leadership, working upon a foundation of education towards the new ideals of world co-operation, can alone avert a dangerous setback.

The necessity of preparation for the changes in the ordering of society which must follow after the War was the basis of the proceedings of the second day of the annual conference of the Labour Party. The Party has a Central Committee on Post-War Reconstruction, on behalf of which a resolution was submitted affirming that "there must be no return after the war to an unplanned competitive society", and setting forth the broad principles of socialization which, in the Committee's opinion, are necessary to avert the danger. Measures of Government control have been found necessary for mobilizing the national resources in war and, it was affirmed, they are no less necessary for securing their best use in peace. While the amount, and method of exerting, such Government control, are highly controversial political questions which cannot appropriately be discussed here, the fact that the Labour Party has set up a committee to study such questions is encouraging, in that it will help to turn the minds of many, who might not otherwise give much consideration to the matter, to the urgent problems of a new world order.

While economic and political aspects of reconstruction plans were naturally prominent topics at the Labour Party Conference, the problem of the best utilization of the land and immediate post-war relief for Europe were also discussed. Sir John Orr has demonstrated the significance for the future of adequate food, proper housing and employment (see NATURE, April 11, p. 401). His own work, and that of other students of nutrition, has shown that a substantial proportion of the population of the world are living below or at the poverty line, and he has outlined a broad scheme for the improvement of conditions. The fundamentals of all such plans are based on scientific progress. Science has provided the knowledge required to improve beyond measure the well-being of humanity; but that is not enough. Scientific workers cannot stand aside when they see the fruits of their studies put to wrong uses. Herein lies a great opportunity for education and leadership. Deference is paid by word of mouth and in writing to the importance of science and scientific method in plans for the future, but there must be deeper appreciation among the rulers of the nations of all that is involved. The word 'reconstruction' must not become a shibboleth; indeed in some ways it is a misnomer, for many of the things which are passing away are outworn or have otherwise served their day. The old world order has failed to provide man with the conditions under which he can live a full life; a new order is imperative to serve the progress of civilization.

It is therefore all to the good that men everywhere should be discussing the framework of world affairs which they will wish to build. The most that can be done—and it is of vital importance that it should be done—is that the opportunities which will be afforded by the fluid state of international affairs should be widely discussed now. Thus the sacrifice inevitable in raising the standard of life throughout the world will be understood and accepted as part of the duty due from every citizen dwelling under the banner of the 'four freedoms'.

RESEARCH ON ELECTRICAL SURGES

Surge Phenomena

Seven Years' Research for the Central Electricity Board (1933–1940). (Reference S/T 35.) Pp. viii+426. (London: British Electrical and Allied Industries' Research Association, 1941.) 50*s*. net.

UNTIL the advent of the Grid erected by the Central Electricity Board during the years 1928–33, there were very few high-voltage distribution lines in Great Britain. Most of the electricity used was generated in the immediate neighbourhood and distributed by cable networks so that electrical disturbances of atmospheric origin could not affect the supply system. This situation was changed in two directions when the 132-kv. network of transmission lines was erected; in the first place, the network itself was subjected to the effects of lightning discharges which could cause damage to insulators, switchgear and transformers, and secondly, surges on the high-voltage lines were transformed at generating and distributing stations and were passed on to the lower voltage distributing systems, which hitherto had been immune from externally produced surges. Thus the Central Electricity Board and the local electricity supply authorities became more painfully aware of the effects of surge phenomena and supplied a considerable impetus to the activities of the British Electrical and Allied Industries' Research Association in its general study of surges.

The large manufacturing concerns had encountered this aggravation of Nature in overseas markets, where long-distance high-voltage transmission had been established for many years, and they had taken effective steps to minimize breakdowns due to lightning, so that much of the electrical apparatus supplied to the Grid benefits from this earlier experience. But in spite of this, there were many gaps in our knowledge of the origin, propagation and effects of surge voltages, and it was to fill these gaps that the Electrical Research Association planned an extensive programme, for which it secured extra financial support from the Central Electricity Board. The E.R.A. reports issued from time to time have been available to members of the Association and some have appeared in the *Journal of the Institution of Electrical Engineers*; but this book under notice is the first public appearance of some of the researches, and it will serve as an invaluable reference book for countless engineers and research workers in applied electricity. There is no other book on the market which treats the general subject so comprehensively, though parts of the subject have naturally been more exhaustively treated elsewhere.

The book covers the threefold aspect of surges: their generation, propagation and effects, and a further section covers the measures in vogue to protect apparatus from the harmful effects of surges and concludes with some valuable recommendations for the protection of overhead lines. Each chapter has been written by a member of the staff of the Association or of one of its contributing firms, or by a member of the National Physical Laboratory, where many of the investigations were made at the instigation of the E.R.A. Surge Committee. Thus the style varies greatly and some of the chapters are not up to date, having been written many years ago and published without substantial alteration, but these defects are not serious. A more serious defect is the concentration of some of the chapters on the E.R.A. activities to the exclusion (in places) of the work of many other investigators; in other words, the book is not the encyclopædia it could have been, emanating as it does from a large research association. Maybe the War is responsible for this; lack of time may have prevented that general detailed supervision so requisite to uniformity and comprehensiveness.

The book opens with a brilliant review of our knowledge of lightning, a chapter hot from the technical press. Papers on lightning have appeared from the pens of physicists, meteorologists and engineers, but never has such a thorough co-ordination been attempted of all data relating to lightning as appears here. Some revolutionary conceptions are introduced, in particular the potentials of thunder clouds to ground, and the nature of the stepped-leader stroke discovered by Dr. B. F. J. Schonland in South Africa. It is even suggested that the nature of the lightning flash may be modified by the resistance of the point of contact of the flash to ground. The authors analyse some of the results of other workers which appeared at variance with established ideas and find a true harmony to exist. There follow descriptions of methods of recording surge voltages and currents, and a chapter on lightning research sponsored by the E.R.A. in Nigeria. Similar expeditions have been equipped in only a few other countries, and it is a matter of regret that the War has necessitated the cessation of this interesting and promising field of research after only two lightning seasons.

Faute de mieux, the E.R.A. has made the best use of man's puny imitation of lightning. Section 2 describes the generation and recording of artificial lightning, or impulse voltages, and the propagation of surges on transmission lines, two lines, one for 33-kv. and one for 132-kv. being made available by the Central Electricity Board for this purpose. The section opens with a mathematical treatment of wave transmission on overhead lines and cables. Lord Rutherford remarked that a mathematical theory is only of use if it gives a clear picture of the physical processes involved. In this chapter the reader is given a very clear picture of the effect on a travelling wave of the many factors encountered on a line: line resistance, line termination, overhead earth return wires, neighbouring conductors, lengths of cable, and corona.

For surges of amplitude below the corona onset voltage, attenuation due to skin effects is not appreciable, although in a few miles from the point of origin the rate of rise of voltage is very considerably reduced. This factor alone must be very beneficial in safeguarding inductive apparatus, in which stress concentration is greatest when the rate of rise of applied voltage is a maximum. If, however, the surge voltage exceeds the corona onset voltage, attenuation is very rapid apart from reduction of rate of rise of voltage. Thus in an example worked out in this chapter, a wave of ten times the corona voltage is reduced to one of five times the corona voltage in two miles. This chapter is well supported by the chapters describing tests on a 33-kv. and a 132-kv. line. In each case, below the corona limit attenuation was found to be small, so that waves propagated just below the corona value will probably reach terminal stations and be doubled by reflexion. These values may be serious for owler-voltage installations but not for the high-voltage lines where the margin between operating voltage and corona voltage is meagre. Above the corona limit, the oscillograms show how the travelling wave is sheared off, resulting in a pronounced change of wave shape which renders the surge far less harmful. The voltages induced in neighbouring phase conductors were studied on both systems, and it was shown that the induced waves might have amplitudes large enough on reflexion to cause sparkover. It appears certain that 3-phase surges will frequently be encountered at terminal stations. The section also includes a description of the apparatus used in the study of surge propagation, namely, the impulse generator and cathode-ray oscillograph.

Section 3 deals with surge voltage distribution in transformers, a subject on which there is an extensive literature but one on which finality has not been reached. The main contribution in this section is the study of the effect of increasing the end-turn insulation in transformers, and the old deduction that the provision of additional insulation on the end-turn does not incresae the safety of the winding is redetermined by a careful oscillographic study. Unfortunately, the results are not substantiated as one would like to see them, by actual tests to breakdown of normal and reinforced insulation. The transference of surges from one winding to another is skilfully handled, and the specially dangerous conditions relating to the open-circuited transformer are emphasized. The subject is very complicated on account of the wide variety of transformer designs, and the treatment here deals only with the straight concentric winding. Manufacturers will be aware of the great difficulty of extending these results to the many cases of complex windings encountered in practice.

The section on surges on insulation deals only briefly with a few classes of insulation, solid dielectrics, cables and insulators. It is of interest to note that in the brief reference to co-ordination of line insulation, the insulation levels for the main part of the transmission line, the line near stations, and the protective gap of the station are separated by good margins of 25–30 per cent, instead of the meaningless margins of about 10 per cent which have been discussed elsewhere in the past.

The fifth and last section deals with the measures employed to protect against the harmful effect of surges. These consist of means for diverting lightning strokes from electrical apparatus, and means for reducing the amplitude or gradient of the surge voltages arriving at electrical apparatus. The critical résumé of the literature on the protective range of lightning rods brings out the danger of basing deductions as to the probable behaviour of lightning on tests carried out on models. It is unfortunate that the chapter does not give more data on the effect of different dispositions of earth wires relative to the three-phase conductors, information known no doubt to the large supply authorities. The various devices in past and current use for shunting surges to ground or modifying their wave shape are described, and tests made on many of these by the National Physical Laboratory are given in detail. The proposed international specification for lightning arresters was under discussion in 1939, and the National Physical Laboratory views on the clauses are given here in the light of experience gained in testing various makes of arrester.

Surge absorbers or wave modifiers were also tested at the National Physical Laboratory. Some behave as capacitors, others as combinations of inductance and capacitance, while a third modifier designed by the E.R.A. comprises an inductance with negligible capacitance to ground, a spark gap in the form of an expulsion tube on the line side of the modifier to ground, and a damping resistance which is switched in parallel with the inductance by another spark gap having a short time lag. Thus up to the instant of breakdown of this latter gap, the voltage rise on apparatus connected to the modifier is determined by the inductance of the modifier and the capacitance of the apparatus, and therefore begins to rise slowly in the 1-cosine form, but after gap breakdown the advantages of damping are realized. The final chapter summarizes the merits of the various protective devices and makes recommendations for system protection under a variety of conditions.

Two aspects of surges are omitted. Practically no reference is made to surges due to switching phenomena, and no observations by supply authorities relating to surge phenomena are given.

T. E. Allibone.

A MYSTICAL PSYCHOLOGY

The Psychology of C. G. Jung

An Introduction with Illustrations. By Dr. Jolan Jacobi. Translated from the German "Die Psychologie von C. G. Jung" by K. W. Bash. Pp. xi+169. (London: Kegan Paul and Co., Ltd., 1942.) 12*s*. net.

THE evaluation of Jung's contributions to psychology and psychiatry is by no means an easy task. His earlier achievements were as scientific as any made before or since in these difficult subjects. His book called "The Psychology of Dementia Precox" was a careful clinical study and showed that he was capable of exact observation. Again, his "Diagnostische Assoziationsstudien", which recorded his careful researches upon reaction times and their relation to unconscious emotion, proved the existence of those constellations of ideas and emotions which he formulated as "complexes". Adler has made so much of the "inferiority complex" (by which he meant feelings of inferiority and not a complex at all) that too often it is forgotten that it was Jung who first conceived the idea of the complex. Nothing could have been more promising than these observations based upon careful measurement. One might have thought that here at last clinical research was attaining definite scientific basis. In spite of this we cannot agree with Dr. Jolan Jacobi that "As a didactic and diagnostic method it has become an essential aid to all psychotherapy and belongs to-day to the standard equipment of psychiatric institutions, clinical psychological training and vocational guidance of every kind, and even finds its use in the law courts" (p. 38). Such a eulogistic description of controlled association is scarcely true—at least in Great Britain—but nevertheless by his careful investigation into reaction times Jung had made what appeared to be a fruitful start.

This work was performed between 1905 and 1907. It was in the following five years that Jung abandoned his clinical work and most unfortunately started upon the study of religions and myths. The result of this preoccupation was the publication of his work on "The Psychology of the Unconscious" which appeared in 1912. It is not exaggerating to state that Jung seems to have forsaken science for religion. This book caused his secession from the Psychoanalytical Society and made a schism with Freud. From then on he formulated his views uninfluenced by others. He developed the idea of the libido existing not as a physical craving as Freud envisaged it but as Dr. Jacobi defines it as "the totality of that force which pulses through and combines one with another all the forms and activities of this psychic system" (p. 50). In practice it appears to erupt in conceptions of gods and demons.

Jung made an attempt to return to clinical medicine in his publication of "Psychological Types", in which he described the extravert and introvert. This phase did not persist, and his later books have tended more and more towards obscurity and mysticism. Dr. Jacobi tries to refute this accusation of mysticism by comparing Jung's psychology with the conclusions of Whitehead and Eddington (although these also have been accused of the same fault) but does not do so very effectively. She says: "Before the word 'mystic' one no longer needs to feel the customary dread—above all, not to confuse it with cheap irrationalism, for it is precisely reason that here presses forward to its own limits, as modern logic likewise honestly attempts to define its own boundaries, not, as it were, by rejecting but by logically establishing the independence, indeed when one has rightly defined and thereby delimited the concept of 'cognition', the sovereignty of the 'mystical'" (p. 64). In spite of this attempt to cut the ground away from the critic, it is difficult to describe otherwise than as mystical and obscure the following passage from Dr. Jacobi's book: "The making conscious of those contents which constitute the archetype of the mana personality signifies therefore 'for the man the second and true liberation from the father, for the woman that from the mother, and therefore the first perception of their own unique individuality'. Only when he in the true sense of the word 'becomes united with God in spiritual childhood'; and then only if he no longer 'blows up' his thus broadened consciousness in order 'thereby paradoxically to lapse into a flooding of his consciousness by the unconscious', i.e. an inflation. Such presumption would indeed, in view of the deep insights he had won, be not astounding; everyone falls victim to it for a time in the course of the individual process" (p. 117).

Well might the reader ask what all this means. Does it imply that the patient might become conceited? One hesitates to say, but Dr. Jacobi states that such nonsense "is likely to have a decisive influence on the formation of the future conception of the world".

If we turn from the consideration of Jung's philosophy to Dr. Jacobi's exposition of it we must admit that her book is thorough and careful. She has made an honest attempt to expound Jung's difficult conceptions, and those who read it will gather some outline of the copious outpourings of the master. The book is divided into three parts: (1) The Nature and Structure of the Psyche; (2) The Laws of the Psychic Processes and Operations; (3) The Practical Application of Jung's Theory. There are a large number of diagrams, but whether they clarify the subject or not it is difficult to say. The book ends with a biographical sketch of Jung's life which seems rather inadequate. There is a complete bibliography (perhaps the most valuable part of the book) which extends to fourteen pages and includes a list of all works in the various languages into which his writings have been translated. There is an index of four and a half pages which seems adequate for a book of this size.

Clifford Allen.

A SOCIAL REVOLUTION

Science and Human Prospects

By Prof. Eliot Blackwelder. (The Thinker's Forum, No. 19.) Pp. 32. (London: Watts and Co., Ltd., 1942.) 6*d*. net.

THE revolution which is in full swing might be dated for Great Britain from mechanical inventions of the latter part of the eighteenth century. She has dealt with scientific and mechanical changes rather than social or governmental, because British history has on the whole been peaceful; but she was able by her resources of coal and iron and the mechanical inventions to beat her neighbours in trade as well as at sea.

It is not necessarily beneficial to undertake a revolution and therefore it would be well in the present movement to specify the good and what might be the better. Prof. Blackwelder's little book suggests some points.

(1) Mechanical force has now been carried almost to the extreme. The steam engine has come into its own. The result of this is the multiplication of the workpeople and the turning of a countryside into a town.

The first fruits of applying science to industry are not all good—great wealth for the proprietors but an ill life for the workpeople. The early part of the last century began the revolution to remedy this. A minimum of welfare was insisted on in factory legislation, and minimum rates of pay were afterwards secured, partly by union action, partly by the State.

(2) The second part of the revolution is ultimately superior. The State by the end of the century had taken education under its care. The English plan in education as well as government is to keep the best of the old and widen as far as resources yield. Although the level is low, knowledge, taste and goodwill to others have increased enormously.

(3) It has often been said that Christianity was never really active until the nineteenth century. And in these later appeals, it is noticeable that freedom is good for health. A benevolent and not dictatorial State is the ideal of the latter part of this revolution. As humanity has come together by the appliances of science, so it must work for higher things in art and music. The outbreak of industrial imperialism which stamped the latter part of the nineteenth century did not aim mainly at the higher things. They are the passionate quarry of the present crusade. A good life for all: any goodness being aimed at, it is seen that religion pervades the whole. Strange that a hundred years ago it was not regarded as irreligious to make fortunes for the few and neglect and degrade the multitude. Is it degrading to work?

The revolution through which we are now passing, aims at something far higher than before. The whole community shares and the State is the ultimate authority; and there will be as many intermediate bodies as needed, for education, for transport, for music and many more agencies, leading always to free initiative.

Beyond this, and more important than this, comes the international body. In this Great Britain will be preponderant, but other States including Germany will have their place. The United States will be at our side and we shall avoid the errors of 1918 in making treaties and excluding the enemy. We cannot believe in a final step back. Humanity which grew out of Western civilization will triumph. It may be long.

F. S. Marvin.

SCIENTIFIC STUDY OF SOCIETY

By DR. HENRY A. MESS
Bedford College for Women, London

The Natural Sciences and the Social Sciences

THE lengthy correspondence in *The Times* a few months ago, a number of articles and letters in NATURE, and the discussions at one or two conferences, all bear witness to the widespread interest in the scientific study of society. They also show a certain amount of confusion of thought and some lack of information as to what is actually being done.

It is natural that there should be this interest at the present time. We have all learned some bitter lessons in the last few years. Among other things we have discovered what great disasters can come upon mankind through science. It was stated recently that one of the first men to fly, an old man now, is heartbroken by the knowledge of what flying has actually come to be. Nobel, who developed the manufacture of high explosives, was similarly saddened by the use to which they were put.

But we cannot turn our backs on science. Nor is it the development of science which is the real evil; it is the lop-sided development of science. It is the rapid growth of the natural sciences without a corresponding growth of the social sciences which has brought such dangers and disasters on us. This is now generally recognized, not least by the natural scientists.

The contrast between the competence of men in some directions and their incompetence in other directions has become a commonplace. Men can mould matter and use physical forces with remarkable facility. They have made the fairy tales come true; they can fly in the air, they can travel under the sea, they can penetrate the recesses of mountains, their whispers can be heard across continents and across oceans; they can work wonders with living matter, they can bring into existence new plants and new breeds of animals. Yet with all these powers at human command, there are millions who are imperfectly nourished, millions who are badly housed. Wars persist, more horrible because of our science. In the intervals between wars there is social strife; and we have the bitter paradox that when our manufacturers and our farmers produce abundantly, they are in danger of being ruined by low prices. Recurrent periods of unemployment blight the lives of multitudes. All this we seem to be unable to prevent.

The contrast between achievement and futility is glaring; and it is a challenge. What response to it shall we make? The answer is obvious. Since we cannot turn our backs on science, even if we would, we have no option but to go forward, to apply science to those spheres of human life in which at present we are so incompetent. Inevitably the question is being asked, more and more insistently, whether the application of scientific methods to the study of society cannot give us a control over social processes comparable to our control over physical forces. Can we find a remedy for the evils, of which we are so sensible, in a scientific study of society?

The answer is being given quite rightly that we can; a great increase of knowledge and a great increase of control are certainly possible. But having said that, it is necessary to give a warning. To argue directly from what the natural sciences have done to what the social sciences might do is unsound. The social sciences are bound to be very different from the natural sciences. Their subject-matter is differen The chemist and the physicist have to do wit inanimate things, which do not have moods and will which do not alter just because they are bein examined. The social scientist is dealing with nothin so consistent, nothing so tractable; he is dealin with the relations of human beings, consciou sensitive, wilful, living creatures. If anyone think that we are likely to obtain laws of social development as precise and as little subject to variation a the great physical laws, he will pretty certainly b disappointed. It has hindered, and not helped, th social sciences that some of their practitioners hav made exaggerated claims on their behalf. What ca be claimed fairly is that the social sciences ar capable of helping us to a much better understandin of the present and to a much clearer perception o the possibilities, the impossibilities and the probabilities of the future.

It cannot be said too emphatically that we nee to be clear in our minds as to the distinctive nature and roles of the physical sciences and the socia sciences. The former can contribute much to huma welfare, as also much to human unhappiness; w need to think hard how to make the best of thei contribution, and to do so will call for co-operatio between physical scientists and social scientists. I this the former have a big part to play. But the cannot help much in what is one of the most urgen tasks of men to-day, the analysis of the nature an functioning of societies with a view to increasin our control over social forces. The physical scientist and the social scientists have really very little i common. Of course, they must both be objective and they must both follow the rules of logic. Bu that is about all they have in common. Only har is done if any attempt is made to force the method or the canons of one upon the other. The chemis can experiment and weigh, and he can hope fo exact results. There is only a very restricted fiel for experiment in the social sciences, and the socia scientist is bound to take into account much tha cannot be measured, but can only be assessed hopes and fears, prejudices, the force of custom, th power of ideas. Some grotesque results have bee reached when attempts have been made to measur that which is not really amenable to measurement and, let us repeat, findings must often be stated i terms of alternatives and of probabilities. Fo example, I think that the majority of competen students of local government in Great Britain woul say that *either* local government areas will be revise and enlarged *or* local authorities will decline in powe relatively to the central government departments Again, there is a strong likelihood that a defeate nation will develop within a decade or two a hars and aggressive nationalism; but alternatively i may fall into a state of apathy and accept a positio of permanent inferiority; or, more rarely, it ma bend its energies to finding an idealistic solution of it difficulties, as Denmark did after 1864. It is impossible to say for certain which of these will happen but it is very likely that one of them will happen

The case is rather different with regard to th biological sciences. But here also we need to distinguish between the utilization of their findings fo the advancement of human welfare and the mor specialized task of analysing society. As an exampl of the former, we may take the impact upon publi opinion of the researches of the dieticians. Clearl we are in deep debt to them, and clearly to maximiz the utilization of their work there must be co-operation between physiologists and social scientists. In the same way there is a good deal of psychological knowledge which can be used. So far there is a parallel with the utilization of the work of the physical scientists. But in addition, the biologist and the psychologist have their distinctive contributions to make to social analysis. The biologists can tell us a good deal about the inheritance of intellectual ability, about the effects of marriages between persons of different race, and so on. The psychologists have taught us a great deal about the workings of the human mind, about the way in which the emotions can distort reasoning ; we have such topical studies as Prof. F. C. Bartlett's examination of propaganda[1].

But while biologist and psychologist, and let us add economist, can throw a good deal of light on the functioning of society, and while each of them can do what no unqualified person can do, yet we should be still far short of an adequate analysis of society. In isolation the various social scientists are liable to fall into serious error, as the literature of eugenics and the long-drawn-out controversy with regard to instincts in man abundantly testify. A correct and an adequate analysis of society cannot be made by biologists only, or by psychologists only, or by economists only. There can only be an accurate and an adequate study of society when the different social sciences are related, and when there is team-work between those who practise them. This has always been a first principle of sociology, which is the general study of society.

The scope and methods of sociology are so commonly misunderstood in Great Britain that it is well to elaborate this a little. Comte's doctrine of the "social consensus" needs modification and re-statement; there are more partial autonomies in the social structure than he realized. Yet that there is an interplay of the various parts can scarcely be doubted, nor that it is intricate and important and needs careful study. Such study is undertaken by the sociologist; and because he is always aware of the interdependence of parts, he views society holistically. The objection generally raised is that the sociologist is attempting too much, and that he trespasses on too many fields. If the sociologist attempted to do the work of the biologist, the psychologist or the economist, that objection would be justified. But it is not so. The sociologist accepts the findings of the specialists ; his business is to relate those findings, and to use them in the interpretation of the society which he perceives as a whole ; sometimes also it is his business to make the specialists aware of alternative explanations of social phenomena. Doubtless to do this he requires some elementary knowledge of a number of social sciences, but that is very different to claiming to be an expert in them. It is probably desirable that a sociologist should be really well equipped in at least one specialist social science. That is one of the ways of advance ; another is to secure that an increasing number of specialists in one or other of the social sciences have a background of general sociology.

It should be added that the sociologist has also one or two specialisms of his own, parts of the field of social study which have not been annexed by any special social science. Of these specialisms quite the most important is the study of social institutions. Such a book as Westermarck's "History of Human Marriage" falls within this field.

Practical Applications

When we are considering what practical benefits the scientific study of society might confer upon mankind, it is useful to distinguish between short-range and long-range inquiries. By short-range inquiries I mean those which are concerned with the problems of a particular society in a particular age. For example, the evacuation of school-children during the present War has presented what I should call short-range problems ; the distresses of the Special Areas a few years ago were short-range problems, the many difficulties which arose in connexion with re-housing were short-range problems. The long-range problems are those concerned with social phenomena which are to be found everywhere and always, with such difficult questions as the limits within which human nature can be altered, or the causes of the rise and fall of civilizations.

Now with regard to short-range problems a great deal of advance could be made very quickly. It is largely a question of money ; and if more adequate provision is made for the social sciences we can soon produce and employ men and women who will throw a great deal of light on our social problems, and who will ease greatly the process of dealing with them. It would not be difficult to draw up a list of short-range problems which could be investigated very profitably. Here, for example, are three suitable subjects for inquiry : (1) the difficulties and the effects of migration within Great Britain ; (2) the conditions favourable and unfavourable to the growth of civic consciousness and local patriotism ; (3) the social life of various types of English towns. On all these subjects something has been done, but not enough. There is much scattered material on internal migration in Government publications and in books dealing with unemployment and the location of industry ; there is an interesting unpublished study of assimilation in the East Kent coal-field ; but it cannot be said that there has been any adequate sociological study of this social phenomenon which is as interesting as it is important. With regard to the conditions affecting civic consciousness a great deal can be learned from the experiences of the new housing estates, as Mrs. Durant's fascinating study of the growth of Watling has shown us ; her investigation might have been multiplied many times with great advantage. As to studies of particular towns, it is lamentable that we have not as yet any study of an English town which can be set alongside R. S. and H. M. Lynd's "Middletown" and "Middletown in Transition".

Such studies are not mere academic exercises ; they supply knowledge much of which could be put to immediate use. Sociologists are in a position to render useful service to Government departments and to local authorities. After the War we shall be building a good many more new estates. A sociologist could point out ways of shortening the process by which a mere collection of houses and of families becomes a true society. In the same way, there is bound to be fresh migration, and a sociologist could suggest ways of easing the strains which there are sure to be when men and women go to live among strangers. I venture to prophesy that the quality of social life in our smaller provincial towns is likely to be in the near future a matter of public concern ; here again the sociologists can be of use, though they will be handicapped for lack of those preliminary studies which might have helped them.

---

[1] "Political Propaganda", by F. C. Bartlett.

Much assistance could also be given in the sphere of international relations. Prof. C. E. Merriam, of the University of Chicago, with a team of co-workers, has reviewed the methods adopted in various countries to inculcate patriotism. Quite a deal could be learned from those studies which could be applied to the task of creating as quickly as possible a strong loyalty to a reconstructed League of Nations or whatever other supra-national body there may be set up after this War.

The long-range problems are another matter. With regard to these, the number of men and women who are competent to do effective research is likely to be small, and progress is likely to be slow. But sustained research might in time yield results of quite incalculable value. For example, how little we really know at present about human nature, about its variations, how far it is capable of change, to what extent it is the same always and everywhere. Yet there is a vast amount of material existent in the writings of historians and of anthropologists which, if it were carefully examined, might yield valuable results.

Here let me digress to emphasize the very special case which can be made out for generous support of anthropological research. I am not an anthropologist, but, like all sociologists, I am deeply in the debt of the anthropologists. Their special claim derives from urgency; the material upon which they work, the simpler societies, is fast vanishing; investigations which are not made in the next few decades will probably not be made at all; and these investigations throw light on social structure and on human nature which we are scarcely likely to obtain from any other source.

It is, I think, almost essential for effective study of long-range problems, and for that matter it is often desirable for the study of short-range problems, that there should be team-work. A society is a whole, and it needs to be studied as a whole; and that means either the co-operation of many specialists or the work of a man of encyclopædic knowledge. Men of the latter type are rare, are perhaps likely to become rarer. It is to team-work therefore that we must look more and more. But the planning of work by a team, and the intelligent co-operation of team-workers, both demand that knowledge of the interplay of the different factors in social life which is the special subject-matter of sociology. Everyone praises his own leather, and I do so unashamedly; it seems to me deplorable that the persons in Great Britain who have been appointed specifically to teach sociology can be counted on the fingers of one hand.

Whether that be accepted or not, there is at least widespread agreement that we need to take more seriously the scientific study of society. Concretely, that means better provision in the universities, more chairs and and more lectureships, more post-graduate studentships. It means better utilization of the already considerable knowledge of social scientists, and an enlargement among other things of the number of careers open to them. It means better understanding and more team-work among them. There is also a great work of popular education to be done. We need to increase immensely the number of those who have some scientific knowledge of the nature and functioning of society. When such knowledge is greater, and when it is more widely spread, we shall be on our way to a considerable measure of control of social forces; and we shall increase the use and decrease the abuse of the abundant knowledge placed at the disposal of mankind by the natural scientists.

WEST INDIAN AGRICULTURE

By SIR GEOFFREY EVANS, C.I.E.

Royal Botanic Gardens, Kew

WEST Indian affairs attracted considerable public attention in the period immediately prior to the outbreak of the present hostilities. Severe economic depression and the deplorably low standard of living had indicated that all was not well and general concern was manifested by the Imperial Government. Signs of considerable distress and labour unrest, culminating in disturbances in various Colonies during the late thirties, resulted in the appointment of a West Indian Royal Commission which toured the various Colonies in the Caribbean area during 1938–39, with the object of making specific recommendations. Unfortunately, the report of this Commission has not yet been released, but the main conclusions reached and certain recommendations made were published in February 1940 (Cmd. 6174). Now apart from Trinidad, which has a big petroleum industry, and British Guiana, which has developed bauxite mining and to a less extent gold and diamond diggings, all these Colonies depend entirely on the agricultural industry for their prosperity. The recorded opinion of the 1938–39 Royal Commission that "agriculture is the principal source of sustenance and wealth in the West Indies and the standards of life must largely depend on the intensive use of the soil" therefore accurately portrays conditions.

It is obvious from this that the betterment of agricultural practice underlies the whole problem of social and material progress in this area. The problems involved are intricate and not easy to solve, and it is opportune, therefore, that H.M. Stationery Office should have been able, even in these difficult times, to publish a book entitled "Agriculture in the West Indies" (Colonial No. 182), which gives a very complete and up-to-date description of conditions as they were just prior to the commencement of this War. The book has been compiled by Dr. H. A. Tempany, agricultural adviser to the Secretary of State for the Colonies, from documents supplied to the West Indian Royal Commission, and from other sources. It forms a valuable record of agricultural conditions in each Colony at the present time besides giving historical data which undoubtedly have considerable bearing on the existing state of affairs.

Unlike most other tropical areas, the West Indies have had no tradition of native agricultural practice to build upon, for the native Indian tribes rapidly disappeared under the Spanish rule which was established at the end of the fifteenth century, and the labour required for development was afterwards met by the importation of Africans and later, after the abolition of slavery, by indentured labour from India and to a lesser extent from China and the Portuguese Atlantic Islands.

As is pointed out in the book referred to above, the system of agriculture is really based on the methods in vogue in Great Britain and the European Continent before the great renaissance of the eighteenth century, with its development of rotations and mixed farming, took place. The negro brought few ideas with him, but perhaps insufficient credit has been given to the changes that have been introduced by the immigrants of East Indian origin. For example, it is perhaps not too much to say, that without the help of their traditional art, the development of the rice industry, which shows considerable progress in British Guiana and could, with a little encouragement, be developed much more in parts of Trinidad and Jamaica, would probably never have taken place so rapidly as it has, for the man of African descent has shown little inclination or aptitude for this type of cultivation.

Throughout the last three hundred years, agriculture has been based on the plantation system, which was first established by the Spanish, and later continued by the French, English and Dutch, when they in their turn began to acquire interests in the islands. Under this system, the land belonged to the planter, who farmed the whole estate with the aid of labourers. The latter owned no land and were not encouraged to cultivate crops for themselves. The crops raised were mainly for export. Sugar-cane has always been the staple plantation crop, and the prosperity of the West Indies may be said to have depended to a large extent, as in fact it does to this day, on the condition of the sugar industry.

Other plantation crops have had their ups and downs. Thus, cotton was cultivated on a large scale at the time of the American Civil War when supplies from the United States to England were interrupted. It ceased to be profitable when peace was declared, and all the memory that is left of it on many of the islands is hillsides covered with poor secondary bush, which are eloquent of the soil erosion that must have taken place during that period. The cacao plantations were started later during one of the periodic depressions in the sugar industry, much of the planting being done at the end of the last century and the beginning of the present one. Cacao is still a major crop in Trinidad, Tobago and Grenada, but is at present in a depressed condition owing to competition from West Africa and Brazil and the ravages of disease.

The cultivation of bananas for export began in a small way in Jamaica during 1868–69. It is somewhat curious that, like sugar-cane, it is not a native of the area, as the Gros Michel banana, which is the commercial variety, undoubtedly originated in the Far East. With the development of better methods of transport, a huge export trade arose and the average exports for the three years previous to this War were in the neighbourhood of twenty-three million stems a year. Now the banana in its turn has become subject to diseases and many growers have had to try to turn to other crops, and, as is the case with cacao, some of the land is going back to cane.

All through their known history, the West Indian territories have been subject to periods of intense depression, which have necessitated the holding of special commissions and inquiries. Prior to the recent commission, probably the most important one was the Royal Commission of 1897 because it did result in certain definite changes for the better. The sugar industry at the time was in the depths of depression; competition with beet sugar, grown under a system of bounties on the continent of Europe, was being severely felt and the Bourbon cane, which was the principal variety, was succumbing to disease. The Commission recommended the thorough overhauling of the sugar industry, the abolition of the sugar bounties, greater diversification of agriculture, the establishment of small holdings, together with the encouragement of peasant agriculture and the placing of scientific research on a proper basis. Many of the proposals were in part at any rate carried into effect. The sugar industry was overhauled and much centralization took place, leading to the amalgamation of many small estates, the adoption of better methods, and higher extraction in the factory. The sugar bounties were abolished in 1903.

An Imperial Department of Agriculture was established in 1898 and the cost of the operations were paid by the Home Government for ten years. Its headquarters were at Barbados, and it operated chiefly in the Windward and Leeward Colonies, but its influence and the results of its researches were felt throughout the archipelago. Much was done to encourage diversification of crops, one of the outstanding successes being the establishment of the Sea Island cotton industry, which is proving its value for war needs at the present time. New varieties of cane were introduced and cane-breeding operations fostered; chemists began to examine the soils and pathologists to investigate plant diseases and pests. In due course similar departments were organized for Jamaica, Trinidad and British Guiana, and in fact most of the agricultural departments now functioning in our tropical Colonies may be said to have had their inception and to be modelled upon the old Imperial Department of the West Indies.

The 1914–18 war period brought high prices and prosperity to the West Indies. The witchbroom disease had not yet appeared in Trinidad's cacao fields, which were at that time in their prime. Panama disease and the Cercospora leaf-spot did not then worry the banana plantations of Jamaica, and the lime producers of Dominica and St. Lucia obtained good crops and good prices, as the wither tip disease only appeared later. But after the short post-war boom, prices fell to a catastrophic extent and in many cases it appeared that the old plantation system was breaking down and would be unable to cope with modern conditions unless considerable modifications and adjustments were made.

The demand of the peasants to own land has been strongly in evidence for years past. It was brought forward at the time of the 1897 Commission, and following its recommendations, some land settlement was actually started in St. Vincent and other islands. These early settlements were comparatively few in number, but their history is interesting and the experience gained should prove most useful at the present time when, as a result of the work of the latest Commission, the need for the development of peasant agriculture has again been stressed. It is not too much to say that the early settlements were not an unqualified success; many of them proved failures due to lack of accurate information and knowledge of the underlying factors involved.

One of the reasons why the demand for land settlement has become so persistent in recent years is the increase in population. Formerly, an appreciable proportion of the labouring population found an outlet for their energies in neighbouring countries. A number emigrated and others found profitable employment for periods of the year in the cane fields of Cuba and other countries. It must be remembered that West Indian labour was largely drawn upon for the construction of the Panama Canal and the opening up of the oil industry in the Central American Republics. These developments offered employment at lucrative rates. The money thus earned enabled the labourer to maintain his family and household in his native island and resulted in the inflow of an appreciable amount of wealth from outside. Within the last ten years or so, this state of affairs has come to an end and immigration laws have curtailed the activities of the West Indian, who nowadays is forced to try to find his living in the British Colonies.

The difficult problem of finding a livelihood has, therefore, become aggravated. Some of the islands are really densely populated. For example, Barbados, which is about as big as the Isle of Wight, has a population of 1,163 to the square mile; Jamaica, the largest island, had a population of 1,173,600 in 1938, with a density of 263 per square mile, and had increased its population by more than 300,000 in eighteen years. For countries which depend entirely on agriculture and have no industries to speak of, these densities are high. The possibility of relieving the pressure by emigration has exercised the attention of many administrators in recent years. Unfortunately, the other islands are mostly already fully occupied and offer little scope, and the possibilities of the two mainland Colonies of British Guiana and British Honduras have frequently been considered. These two Colonies certainly have the area, and on that basis alone are considerably under-populated. The same might very well be said of Australia.

If one examines the facts, however, it is found that although British Guiana covers an area of about 90,000 square miles, and is, therefore, larger than England, Scotland and Wales put together, eighty-seven per cent is under heavy tropical forest, ten per cent under savannah, and only three per cent on the coast is cultivated. The old idea that land producing heavy rain forest in the tropics must be fertile has been largely exploded, and as a matter of fact the soil underlying these British Guiana forests is singularly poor, and as the few experimental settlements have proved, is incapable of supporting permanent agriculture. The same may be said of the savannah soils. These are also infertile and lacking in essential mineral salts. They at present support a small ranching industry, and it would seem that future developments would lie in the direction of improving the methods of cattle raising. It is possible, even, probable, that the forestry industry may be scientifically exploited after the War, even though tropical rain forests are difficult to develop commercially because of the multiplicity of species they contain. Neither the cattle industry nor forestry will, however, be in a position to afford relief to the congested populations of the islands, even if the latter could adapt themselves to work which is specialized and to which they are not accustomed. In British Honduras again, forests predominate, and the evidence is that good agricultural land is strictly limited.

The best means of helping British Guiana at present lies in providing proper irrigation and drainage facilities in the frontal lands, with the view of developing land settlement with paddy as the basic crop, as the conditions are specially suited to this kind of cultivation. The peoples of East Indian origin are skilled in this form of agriculture, but it is more than doubtful whether immigrants from the islands, the majority of whom would be of African descent, would be able to settle down to it. It will be seen, therefore, that the two mainland colonies do not seem to present an easy solution to the over-population problems of the islands, and it is evident that these islands will have to try to find the solution within their own confined boundaries, so long at any rate as the present social and political restrictions affecting emigration continue.

There is no doubt that many of the islands could support a larger population if all the land available for agriculture were properly utilized. As already indicated, many of the plantations have become derelict and many others are not producing anything approaching their maximum. In many instances the estates are heavily in debt, with the result that considerable capital expenditure would be necessary to make them once more productive. But the owners usually find it impossible to obtain the necessary money to provide for the drainage and replanting and similar operations essential to maintenance of production. The long period of depressed markets has found the owners already mortgaged, and in many cases they continue to use out-of-date methods, so that they are in no condition to tide over bad times. The sugar industry has been able to carry on, though with difficulty, because the smaller estates have combined, the factories have been centralized, modern machinery installed, and scientific inquiries sought and new methods adopted. This was not the case with the cacao, the lime, and, to a less extent, the coco-nut plantations. These crops do not lend themselves so readily to centralization, and as a result many of them have become derelict. It has long been evident that some drastic measure would be needed so that the proper utilization of the available land might be able to meet the situation created by the rising population. Change of ownership and experiments in land settlement with peasant smallholders seem to be the inevitable outcome.

Another matter that has given grave concern is the great dependence of the islands on imports for the food supply. The tradition of the West Indies has been to grow crops for export. In Barbados, for example, the estimated value of the food crops actually home-produced in 1938 was about £135,000, while in the same year the food imports were £516,000 and animal foodstuffs another £78,000. Further, much of the food imported was not of high nutritional value, with the result that the public health authorities were gravely concerned about the malnutrition that was evident. The other Colonies show a similar dependence on imports for their food supplies, although to a less spectacular degree. These islands would be in a serious quandary if anything should happen to upset the smooth working of the shipping lines, as is likely to happen in time of war. A change of policy has, therefore, appeared in the last few years, hastened of course by the advent of the present War, but already seriously considered for some years previously. It is now generally accepted that these Colonies must be more self-supporting in food supplies and should endeavour to produce food of better nutritional value than much of that which is now imported.

The decision to open land settlement was made before the War, and the Governments of the most densely populated islands are taking the steps within their means to acquire suitable estates and settle them with peasants on small holdings. St. Vincent made a start at the beginning of the century. Jamaica has recently done much in this connexion, as in 1938 a sum of £650,000 was raised on loan by the Government to extend settlement further, and a separate Department of Land Settlement was formed. In the Leeward Islands, also, a good start has been made by the purchase of estates in Nevis and Antigua, and the other Colonies have taken similar action. It may be taken, therefore, that a commencement has been made; but it is necessary to sound a word of warning since the technique of successful land settlement in the tropics is not easy, and has many pitfalls. There is the matter of the form of land tenure, for example.

The demand for freehold is great. Naturally, everybody wants to own his bit of land, but Government has definite responsibilities in this direction that cannot be disregarded. It must be remembered that land is precious in the West Indies, and the pressure of population is great. Experience with the older land settlement has shown that there is a tendency to exploit the land. Steep slopes have been deprived of their tree cover for cropping, with the result that much of the soil has been lost and periodic floods have caused destruction lower down. Repeated cropping, without manuring, has impoverished the land, and so on. One could mention some of the older settlements of the islands where the land has been completely ruined in fifteen years and the settlers have then demanded to be placed on fresh land. Instances of this sort can obviously not be repeated on a large scale, because the area of cultivable land is limited and the soil once lost cannot easily be replaced, and so the time might arrive when there would be no worth-while land left for anybody.

In fact, the sooner it is recognized that the soil is the main, and in many cases, the only asset the islands possess, the better it will be for everybody, for once lost it cannot be recovered. The granting of freehold is a matter that needs very serious consideration, therefore, but whatever form of tenure is finally selected, reasonable security must be offered, so as to give the peasant the chance to improve his holding. Without such security, there will be the natural tendency to 'skin' the land. On the other hand, the Government must be in a position to remove anyone who disregards the rules safeguarding the land and adopts methods that result in soil erosion and impoverishment.

The plan is to adopt a system of mixed farming, involving rotational cropping and including the keeping of livestock. The main object of introducing livestock is to provide for a supply of pen-manure and so keep up the humus content of the soil. Under the high temperature and moist conditions of the wet tropics, the soil loses its organic contents far more rapidly than in temperate regions. The details of cropping have yet to be worked out and the size of the holdings will naturally depend on circumstances such as the locality and soil, size of holdings, and availability of irrigation water. It will be necessary that the peasant should be mainly self-supporting so far as food is concerned. On the other hand, he must be able to grow some crops for sale, otherwise he will not have the cash to provide himself with the necessities of life, such as clothing and amenities, nor will he be able to pay his rent and the taxes which are necessary to maintain the governmental and social services.

The class of livestock suited for peasant holdings requires special consideration. The cow is obviously essential, but the type has not yet been finally decided, although a good deal of work has been devoted to livestock in recent years, particularly in Trinidad and Jamaica. In these two Colonies, experiments have been made to grade up local stocks by the use of high-grade dairy breeds of European origin. The Holstein (Friesian) is the breed favoured in Trinidad, and several breeds, including the Channel Island types, in Jamaica. It has been found that the introduction of European breeds has tended to produce a type that is not really suited to the tropics, as, quite apart from the question of resistance to disease, the respiratory organs are not suited to the heat of the tropics. Efforts to improve matters in these respects are now in progress, using Zebu blood, and undoubtedly considerable progress has been made in producing superior milking cattle. The movement to establish dairies for the production of good milk for supply to the towns has increased of late years and cows bred for this purpose are supplying the gap. Under dairy conditions, however, the cows receive every care and skilled attention and a lot of supplementary and high-grade foodstuffs. Under peasant conditions, such will not be the case, and the cow will have to forage for itself, its food being supplemented with fodder crops and surplus waste from the peasant's holding. The peasant is not likely to be in a position to buy hard grain or cake from outside sources. It is difficult to imagine, therefore, that the large-framed cattle bred for dairy purposes will prove really suitable for the peasant, and one would like to see attempts made to solve the problem by careful selection from the common cows of the countryside.

It is true that there are no indigenous cattle in the country, but they were introduced several hundred years ago by the Spaniards, and running all through the islands one comes across small, shapely beasts, somewhat resembling some of the Channel Island breeds, which are thoroughly hardy and acclimatized and might prove the basis of such a breeding herd as is contemplated. Finally, there is the buffalo. It has been introduced into Trinidad on the sugar estates, but is used solely as a draught beast. Its value as a milch animal is not appreciated, yet in India and the East the buffalo cow is regarded as a fine milking beast and is highly prized as such. In the Colonies with large populations of East Indian descent at any rate, there would appear to be a reasonable prospect for its utilization as a milk-producer.

The details for the consummation of this programme of agricultural reform are now being worked out by the recently appointed Inspector-General of Agriculture, working within the organization set up by the Comptroller for Development and Welfare in the West Indies. The task is immense and one of the difficulties lies in the great variety of climate, soil and conditions that occurs in the various colonies. Each one differs from its neighbours to a remarkable degree, and each has its own peculiar problems. The difficulty of providing staff adequate to tackle the problems involved is enhanced by the number and often the small size of the units concerned. The larger Colonies, such as Jamaica, Trinidad and British Guiana, are in a position to maintain agricultural departments adequately staffed, but the smaller islands cannot afford this, and means will have to be found to pool their resources, and to provide the Inspector General of Agriculture with the necessary staff to carry out essential field experiments, to work out systems of cropping, demonstrate the results of research activities, teach the elements of animal husbandry, and arrange for the orderly marketing of the crops produced.

Many of the problems call for research in the first instance, and up to the present their investigation has not always proved possible. Research work is, in future, to be centralized at the Imperial College of Tropical Agriculture in Trinidad. This institution, after a life of some twenty years only, has already established for itself an enviable reputation and is regarded as the centre for agricultural knowledge, not only by the British Colonies, but also by the Latin American Republics that border the Caribbean Sea, and it has in addition strong cultural ties with the United States and Canada. Already its hands are full, for in addition to a heavy programme of long-range research, it is the centre at which agricultural cadets receive their training for work in the agricultural departments right through the tropical Colonies of the British Empire. The College also trains men for agricultural work in the West Indian area. If it is to be charged with a number of specific West Indian problems in addition, it will need a good deal more financial support, and will have to be expanded. It is undoubtedly the best place at which to carry out the contemplated researches, and, given adequate funds and the necessary increase in staff, there is no reason to doubt that it will fulfil its task.

The West Indies appear to be on the verge of great new developments. The traditional economic system which depended on the production of export crops and the import of food needs modification. Efforts must be made to render these Colonies far more self-supporting in their food requirements than has been the case in the past, for it is believed that a country which is self-supporting in food is far better able to tide over the periodic trade depressions which inevitably occur, since during such periods the export crops may have to be sold at prices far below cost of production or difficulty may even be felt in disposing of them at all. In either case, there is little enough money available to purchase even the bare necessities of life. So, the next few years may see a radical change in the West Indies in the direction of a more rational system of agriculture, having as its main object the better utilization of the land and the preservation of the all-important soil. The policy of settling people on small holdings will be accelerated with the main object of making these Colonies more self-supporting as regards food. In order to effect this, some of the estates which are redundant, or cannot be worked profitably as plantations under existing economic conditions, will have to be taken over and settled with small holders. This does not necessarily mean that the plantation system as a whole with disappear. Many of those which are favourably situated, such as the sugar estates in the larger islands, must continue, and should benefit because the change should result in a more assured supply of labour from a settled peasantry. In fact, a combination of the two systems, each lending support to the other and with interlocking interests, would seem to be the happiest augury for the future.

CARL VON LINDE

A Pioneer of 'Deep' Refrigeration

By J. H. AWBERY
National Physical Laboratory

CARL VON LINDE is probably known to most scientific workers as the designer of a liquid-air machine, and nothing else. He contributed, however, to ordinary refrigeration as well, and still more to the problems of gas separation which are now becoming of such technical importance. Thus it is fitting, in this year which sees the centenary of his birth—he was born on June 11, 1842—to survey his work and to realize the debt which we owe to him.

It was in 1876, when he was thirty-four years of age and professor of thermodynamics at Munich, that Linde took out his patent for an ammonia refrigerating machine. Before this, machines using ether had been used (they are now obsolete), as well as bulky and inefficient cold-air machines; but Linde had the scientific knowledge to calculate the thermodynamic efficiency attainable with different media, and the technical skill to design the plant well—so much so that Ewing, writing in 1908, was able to say: "The design of the Linde machine has been carried out with conspicuous care, and it owes much of its great success to excellence in mechanical detail". From the time of its introduction until recent years, the ammonia machine has been the most widely used refrigerating plant for all purposes except marine work, where carbon dioxide (which also was introduced by Linde, though independently by others) was preferred for various reasons. In recent years, the advent of the turbo-compressor has led to the use of organic refrigerants for air-conditioning work. The wide demand for small domestic plants has also been associated with the use of organic liquids, so that ammonia, though still widely used, is less dominant than formerly.

When he began to work on the production of liquid air, Linde had a clear idea of using it to produce oxygen by fractional distillation, and probably saw this as more important than the attainment of very low temperatures. At the time, air had already been liquefied by various investigators using a number of methods. Linde, in 1893, used a process not unlike that of the ordinary refrigerating plant, but with a heat interchanger to make the cooling cumulative. The air to be liquefied is compressed to a high pressure, cooled by circulating water, and then expanded through a throttle valve. (It is at this point that the process used by Claude differs. In Claude's arrangement, the gas expands in a cylinder and is made to do work so that the process is nearly adiabatic.) Here the temperature falls owing to the unresisted expansion. The cooled air leaving the valve then passes away up the outside of the pipe along which the air flows to the valve; thus the following air starts its expansion at a lower temperature. In this way, the air leaves the valve at continuously lower temperatures, until at last the boiling point is reached, and some of the air liquefies. From this time on, a steady state is approximately reached, in which part of the air leaving the valve flows away in the gaseous form, and may be regarded as the refrigerant, which completes its thermodynamic cycle by warming up to atmospheric temperature, while the remainder is liquefied.

The details of the process have, of course, been modified, but in principle Linde's first apparatus has been closely followed in subsequent design, and has been the basis, not only of liquid-air plants on a large scale, but also of plants for the liquefaction of hydrogen.

One of the two main deviations from the simple process outlined above consists in avoiding the waste which results from the expansion of all the air from high pressure to atmospheric. Actually, it is only that part of the air which is to be drawn off that need be lowered to atmospheric pressure. The remainder, which acts as the refrigerant, can be kept at a much higher pressure, thus greatly reducing the work of compression. To this end, the air at about 200 atmospheres is expanded to 40 atmospheres, and only that part which is to be drawn off is afterwards expanded to atmospheric pressure. It is found in practice that this increases the amount of liquid air obtainable for a given input of energy by about 10 per cent.

The other economy is to cool the air, before compression, by means of a subsidiary (ammonia) refrigerating plant. When the two modifications are used together, the efficiency is raised from about 0·1 gallon per kwh. to 0·3 gallon per kwh.

As mentioned above, Linde undertook the design of a liquid-air plant originally with the idea of using it to extract oxygen from the air, as an improvement on the chemical method then in use. His first really successful apparatus was described in 1902, and utilized the principle of the familiar rectifying column. This depends for its action on the facts that liquid and vapour in equilibrium with each other have different compositions, and that the boiling point of oxygen is higher than that of nitrogen. Thus a liquid with 20 per cent nitrogen and 80 per cent oxygen is in equilibrium with a vapour containing 52 per cent nitrogen and 48 per cent oxygen, while liquid with 80 per cent nitrogen and 20 per cent oxygen corresponds to a vapour with 95 per cent nitrogen and only 5 per cent oxygen.

In a simple rectifier for the production of oxygen, the liquid air, at a temperature just below its boiling point, enters the top of the column, consisting of a chamber stacked with glass balls, over which it trickles to the bottom. The liquid in the column meets a rising stream of oxygen, which is itself cooled and condensed, thereby giving up heat which evaporates nitrogen from the down-flowing liquid. The latter thus becomes progressively richer in oxygen, until at the bottom it consists of nearly pure oxygen. Arrangements are made to draw off the gas from the liquid which collects at the bottom. In its path, it is used to cool the incoming air, and similarly the nitrogen which escapes from the top of the column is made to act as a cooling medium before it finally escapes. By the nature of the process, if pure oxygen is required, the escaping nitrogen is far from pure; conversely, if the rectifier is operated so as to obtain pure nitrogen, then the oxygen is impure. To obtain both elements pure would require multiple rectification, in which the products from both ends were separately redistilled, and it is not at present commercial practice to make both gases in one plant.

It should be noted that the operation of a rectifying column so as to produce pure nitrogen involves appreciable modification. Instead of collecting the desired product as a liquid at the bottom, and allowing some to evaporate, it is then necessary to collect the gas at the top and to condense some of it to provide a downflow of the liquid. The device suitable for this purpose was introduced by Linde some eight years after his first rectifier, and is described as the Linde double-column rectifier.

In the early days of this subject, the only product of commercial importance was oxygen, which is now used (for example, in welding) on an enormous scale. In the last twenty years, however, the demand for nitrogen has become equally important, in view of its use in synthesizing ammonia. When it is required for this purpose, the plant which liquefies and rectifies the air is invariably on the site of the synthetic ammonia works, and the nitrogen merely flows along a pipe line from the rectifier to the point where it is used. Nitrogen of purity 99·96 per cent is now manufactured commercially, without the necessity for any chemical treatment.

This development would have astonished Linde, to whom the nitrogen was not only a troublesome impurity, but the more so on account of its being present to the extent of four fifths of the whole raw material. His astonishment at the rise of nitrogen to an importance such that the two gases are now prepared in roughly equal quantities, would be small compared with his amazement if he could learn that some air is now liquefied for the sole purpose of extracting argon from it, and that there is every likelihood of a thriving industry growing up to extract krypton and xenon—gases which are present in the atmosphere to the extent of 1·1 and 0·08 parts in a million by volume.

Up to the present, the demand for argon arises solely from the needs of the gas-filled lamp, where its high molecular weight makes it of value in preventing the evaporation of the filament, and thus enables the latter to run at a high temperature and a correspondingly high luminous efficiency. Although the gas-filled lamp was only introduced about twenty years ago, its importance may be gauged from the fact that some thousand million such lamps are now made annually.

To separate argon from air, the latter is first fractionated into two components, an argon-oxygen mixture free from nitrogen and an impure nitrogen, which is rejected. The mixture of argon and oxygen is then rectified, by apparatus of the same type as that used in simple rectification; the argon so produced contains the residual nitrogen from the oxygen-argon mixture, the oxygen being practically free from nitrogen and containing about 0·2 per cent argon. The oxygen, of course, is not wasted; it is in fact an economic necessity to obtain a second product when the necessary large volumes of air are being treated to extract the 1 per cent argon which they contain.

Helium and neon have boiling points far below those of argon, oxygen and nitrogen. Hence they remain in the gaseous form, and accumulate at the top of the separating column. It is in some works found profitable to collect these gases from time to time, since neon is, or was until the black-out, in demand as a filling for the gas discharge tubes of striking red colour widely used for advertising purposes.

It is clear from what has been said above that Linde was one of those pioneers whose work was so well done that it could bear extension in many directions: for many of the later developments, carried out since his death, have retained his methods with only minor modifications.

OBITUARIES

Sir Joseph Larmor, F.R.S.

JOSEPH LARMOR was born at Magheragall, Co. Antrim, on July 11, 1857. In his schooldays at the Royal Belfast Academical Institution, he is described as a "thin and delicate black-haired boy of most precocious ability both in mathematics and classics". He gained a scholarship at Queen's College, Belfast, where he graduated with the highest honours. From there he proceeded to St. John's College, Cambridge. A severe illness made it necessary for him to lose a year; but he took the Mathematical Tripos in 1880 and came out Senior Wrangler, J. J. Thomson being second. Larmor was at once appointed professor of natural philosophy in Queen's College, Galway. He was there during 1880–85, and then returned to St. John's College as lecturer. In 1903 the Lucasian professorship fell vacant through the death of Sir George Stokes; Larmor succeeded him, and held the famous chair of Newton until his retirement in 1932. His last years were spent at Holywood, Co. Down, where he died on May 19.

The researches by which Larmor will chiefly be remembered belong to the years about 1895–1905, which are now looked upon as a transition period. The great wave of expansion of physical science in mid-Victorian times, in which Maxwell, Kelvin, Stokes, Rayleigh and others were prominent, had spent its force. Apart from one or two 'small clouds on the horizon', the classical theories seemed to have been well rounded off; and it was beginning to be said that the possibilities of progress were approaching exhaustion. Later the new conceptions associated with quantum theory and the theory of relativity were to arise, and wake theoretical physics into another outbreak of feverish progress. In the interim, two names stand out prominently, Lorentz and Larmor. Their work has not been effaced by the newer developments. Larmor's results are accepted as fundamentally sound, and are now turned to account in ways which must have greatly perturbed the conservative mind of their originator. The magnitude of his achievement was recognized by the award of the Copley Medal of the Royal Society in 1921.

Of the two rivals in the Tripos of 1880, Thomson was the first to achieve wider eminence, originally as a theoretical physicist but later in experimental researches. Larmor, who always remained on the theoretical side, developed more slowly, and it was not until 1892 that his work gained him election into the Royal Society. From 1894 until 1897 he published a notable series of memoirs on electromagnetic theory in the *Philosophical Transactions*; these form the foundation of his book "Aether and Matter", published in 1900. The purpose was to work out systematically the idea, then gaining ground, that matter is essentially an electrical structure. In particular, the continuous electric fluid of Maxwell was replaced by a particle theory which recognized that electricity, like matter, is atomic in structure. A particle theory of electricity was very much in keeping with the experimental advances of the time, but that seems to have been partly a coincidence. The electron was not discovered experimentally until 1897. In "Aether and Matter" the term electron is used indiscriminately for positive and negative charges, although it was not until twelve years later that this view of the nature of positive electricity became reconciled with experimental knowledge.

"Aether and Matter" is, in substance, one of the greatest of scientific books. It is a difficult book, because Larmor's habitual obscurity of style often makes his published work almost as unreadable as his handwriting. But to the student of the period 1900–5 it was the one gateway to new thought, inspiring and revolutionary. It must not be inferred from the title that it represents a wholly antiquated form of thought. Scientific writers nowadays have to bow to the prejudice which does not allow the ether to be named, and are obliged to use a periphrasis; but the 'resonators' and the 'particles in negative energy levels', now employed to fill the space where the ether used to be, expose the error of those who thought the ether had become unnecessary. Modern progress has modified Larmor's "Aether" no more and no less than Larmor's "Matter".

Of special interest was Larmor's result that, if matter is electrically constituted, any moving object must suffer a minute contraction in the direction of its line of motion. The first suggestion of such a contraction was a brilliant guess proposed by FitzGerald to explain the unexpected result of the Michelson-Morley experiment. In the light of Larmor's theory it becomes no longer a hotly disputed hypothesis, but an immediate deduction from the electromagnetic laws universally accepted. In this and in other developments it is difficult to disentangle the shares of Larmor and Lorentz; and perhaps it is of no great moment to separate contributions which have now become woven together. But, from the account given in Whittaker's "History of the Theories of Aether and Electricity", it appears that the well-known Lorentz transformation was originally given by Lorentz in the form of a first-order approximation, afterwards extended by Larmor to the second order, and finally shown by Lorentz to be exact. Since it is in the second order approximation that the contraction effect is found, it was Larmor's contribution which elucidated it; and we shall perhaps do justice between Holland and Ireland if we speak of the "Lorentz transformation" and the "FitzGerald-Larmor" contraction.

Among Larmor's outstanding contributions were two results continually quoted and used in present-day researches, namely his formula for the radiation of energy by an accelerated electron, and his theory of the precession of electron orbits in a magnetic field. He wrote valuable papers on a variety of subjects including hydrodynamics, waves and the Heaviside layer. He was an enthusiast for the Principle of Least Action as the key-stone of physics, and wrote extensively on the transformation of electrodynamics and other branches of physics into that form.

After his own revolutionary outbreak, Larmor became decidedly conservative in his scientific views. It was difficult to ascertain how much he appreciated the new developments in relativity theory and quantum theory, because he was accustomed to adopt a pose which exaggerated his aloofness. In examining dissertations with him one had always to listen to a tirade against the wild kind of problem on which the modern young man spends his time; but he was generally well informed on the actual subject-matter. My impression is that he followed the new theories very attentively, but always cherished the hope of finding a weak spot in them.

Although his heart was with the physicist of the nineteenth century, Larmor must be counted as the harbinger in England of the new ideas which mark the present century. He was the first to throw off the obsession which possessed an earlier generation—that everything must be explained as though the universe had been made from materials and contrivances similar to those of an engineering workshop. The ether of "Aether and Matter" (a development of MacCullagh's rotationally elastic ether) was not a material fluid possessing density, compressibility or other characteristics of gross matter; it was an entity of a different order with properties describable symbolically, in which the "freely mobile intrinsic strains" were shown to give birth to the commonly recognized properties of matter. It was tempting, after his conservative outbursts, to chaff him as having been the moving spirit in the revolutionary ideas which so much disturbed him—and it is undoubtedly true that his teaching had had great influence in that direction—but it was plain that he did not like the accusation.

Larmor had a strong attachment to his native country. It is no coincidence that "Aether and Matter" is so largely a development of the work of his countrymen MacCullagh, Hamilton and FitzGerald. It was probably his intense feeling over the Irish question which persuaded him to enter Parliament, where he represented the University of Cambridge as a Unionist from 1911 until 1922. He can scarcely have found the position congenial; and it was clearly not the right field for his abilities. His most important work outside the University was as secretary of the Royal Society from 1901 until 1912. As a University teacher, his lectures were obscure, ill-ordered and difficult to follow; but they were well worth the effort to follow. There are doubtless many who can, like the writer, testify to the inspiration which they imparted.

A. S. EDDINGTON.

WE regret to announce the following deaths:

Dr. H. A. Des Vœux, president of the National Smoke Abatement Society, on May 20.

Prof. A. R. Forsyth, F.R.S., emeritus professor of mathematics at the Imperial College of Science and Technology, on June 2, aged eighty-three.

Dr. Emil von Grósz, honorary fellow of the Royal Society of Medicine and president of the International Campaign against Tuberculosis, aged seventy-six.

Dr. John Lindsay, professor of physiology and histology at the Glasgow Veterinary College, aged seventy-seven.

Mr. E. Hesketh, a well-known refrigeration engineer, on May 18.

Mr. R. G. McConnell, director of the Geological Survey of Canada and Deputy Minister of Mines during 1914–20, on April 1, aged eighty-five.

NEWS and VIEWS

National Institute for Medical Research

Sir Henry Dale, P.R.S.

SIR HENRY DALE, who retires from the post of director of the National Institute for Medical Research on September 30, has long been the central figure in some of the most active fields of physiological and pharmacological research. During the years 1906–14, he was director of the Wellcome Physiological Research Laboratories, where he gathered around him a very brilliant team of workers. He then joined the staff of the newly formed Medical Research Committee, which became the Medical Research Council in 1920. He has been the effective head of the Council's laboratories at the National Institute at Hampstead since they were first opened. Under his leadership these laboratories have become world-famous.

Much of Dale's early work centred around the pharmacological analysis of extracts of ergot, which were found to contain, among other things, ergotoxine, tyramine, histamine and acetylcholine, all of which had interesting properties and all of which served as the origins of broadening advances. With various collaborators he showed that histamine and acetylcholine are both normal constituents of the body of mammals, and he has done more than any-one else to establish the significance of these discoveries. The work which demonstrated the relation between acetylcholine and nerve endings won the Nobel Prize for Physiology in 1936, which he shared with Otto Loewi. Many other fields of work have been illuminated by his clear brain and genius for experiment, which have done great service to British medical research not only through his own work and that of his immediate colleagues, but also through advice and help freely given to a very large number of people. He has mainly been responsible for the success of the League of Nations in establishing international standards for the biological standardization of bacteriological products, hormones and vitamins, and a large proportion of the actual international standards are kept at the National Institute.

Prof. C. R. Harington, F.R.S.

PROF. C. R. HARINGTON, professor of chemical pathology in the University of London, and director of the Graham Research Laboratories at University College Hospital Medical School, who is to succeed Sir Henry Dale as director of the National Institute for Medical Research, became well known through his work on the active principle of the thyroid gland, which he started with Prof. George Barger in Edinburgh and continued in University College, London. Thyroxine had been isolated by E. C. Kendall but not in sufficient quantities for accurate chemical work. With various collaborators Harington devised an improved method of isolation, determined its structure, synthesized it, resolved it into its optical isomers, showed that the natural isomer was lævo-rotatory, synthesized a number of allied substances some of which had similar pharmacological actions, isolated from the thyroid gland a simple polypeptide which differed from thyroxine in its absorption from the intestine, and showed that di-iodotyrosine was also present in the thyroid. These different aspects of work on a new active principle are generally shared among many different laboratories, and it is remarkable that one man could do so much.

Later, Harington and his colleagues did important work on crystalline insulin and synthesized glutathione. Recently they have been working on the preparation of antibodies which counteract the effects of substances such as thyroxine and aspirin, by combining these comparatively simple substances with proteins and using the compounds thus formed as antigens. Prof. Harington was appointed a member of the Medical Research Council in 1938; he has been editor of the *Biochemical Journal* for some years. His outstanding qualities certainly justify the Council in appointing, as the director of its laboratories, a man who happens to have no medical degree.

Award of James Watt International Medal

THE Council of the Institution of Mechanical Engineers has unanimously awarded the James Watt International Medal to Mr. A. G. M. Michell, of Melbourne, on the nomination of the Institution of Engineers, Australia, the South African Institution of Engineers, and the Engineering Institute of Canada. The Medal was founded by the Institution in 1936 to commemorate the bicentenary of the birth of James Watt on January 19, 1736, and is awarded every two years to an engineer of any nationality who is deemed worthy of the highest award that the Institution can bestow and that a mechanical engineer can receive. In making the award the Institution has secured the co-operation of the leading mechanical engineering institutions and societies in all parts of the world. Mr. Michell, who was elected a fellow of the Royal Society in 1934, is best known for his work in connexion with thrust and journal bearings, but he has, in addition, made a number of extremely valuable contributions to the science of engineering in connexion with centrifugal pumps and crankless engines. His outstanding achievements as a man of science, a mathematician of international fame, an inventor, and a producer fulfil in a unique way the conditions of the award of the Medal. Without the Michell bearing the high-powered modern ship and the large central power station would scarcely have been possible to-day; and, it is, therefore, most appropriate that the Institution of Mechanical Engineers, which is so largely concerned in the development and application of power, should have recognized the pioneer work of Michell by awarding him this Medal. The last award of the Medal was made to an eminent Continental engineer, Prof. Aurel Stodola, who was associated with the development of the scientific basis of the design of steam turbines.

Carl von Linde, 1842—1934

CARL VON LINDE, the centenary of whose birth falls on June 11, and whose work on refrigeration is the subject of an article by Mr. J. H. Awbery elsewhere in this issue (p. 630), was one of the outstanding German engineers of his time. A lecturer of distinction, he was also a successful inventor, a sound constructor, and an indefatigable investigator. Born at Bernsdorf, Oberfranken, Bavaria, he was the son of a pastor, being the third child in a family of nine. His early training had much to do with his success, and in one of his writings he pays a touching tribute to his mother. From school at Kempen he was able to enter Zurich Polytechnic and there came under the influence of the remarkable trio Zeuner, Reuleaux and Clausius. The lectures of Clausius on heat greatly influenced him. From Zurich he entered Borsig's locomotive works at Berlin, and then joined Krauss's new works at Munich. In 1867 he drove Krauss's first locomotive to the World Exhibition at Paris. Soon after this he became an assistant professor at Munich Technical High School, and it was there that he first turned his attention to refrigeration, publishing in 1871 a paper on "Improved Ice- and Refrigerating Machines". The first machines built to his designs were constructed at the famous Maschinenfabrik-Augsburg, which afterwards built the first Diesel engines and has recently been in the news. On April 5, 1876, he took out his patent for an ammonia machine. His work proved so valuable to the brewing industries that in 1879 he resigned his professorship and founded at Wiesbaden the Gesellschaft für Lindes Eismachinen. A.-G., a concern dealing with the planning and design of refrigerating installations.

By 1891 Linde's success was such that he was able to resume his experimental work, establishing for this purpose a research institute at Munich. In 1895 he produced liquid air on a scale hitherto unknown, and in 1902 he erected the first oxygen works. The company founded in 1879 led to Linde machines being made in many countries. In 1901 a gas liquefaction works was opened at Höllsriegelskreuth near Munich, in 1920 a factory for pumps and compressors was started, at Sürth near Cologne and another branch was opened at Mainz. An energetic member of the Verein deutscher Ingenieure, in 1897 Linde was awarded its highest distinction, the Grashof Medal. He was especially interested in Oskar von Miller's work in founding the Deutsches Museum at Munich, and some of his original apparatus is preserved there. He lived to the great age to ninety-two, passing away at Munich on November 16, 1934. His portrait is reproduced in Matschoss's "Great Engineers" (1939).

Physicists during and after the War

IN his address delivered at the annual general meeting of the Institute of Physics in London on May 28, the president, Sir Lawrence Bragg, spoke of the vital part physicists are playing in the national effort and referred to some of the many interesting applications of the science that have been brought to fruition under the stress of the War. The main part of his address was, however, concerned with the future, and his proposals were based on the assumption that mankind is at present in the throes of one of the great mutations of history. He believes that the oncoming technological age will require many scientific workers to continue as technologists into which they have had to turn themselves in these war years, and he suggested that the present training of physicists will need considerable modification to produce more men suitable for this type of work. Anyone who has had experience as an internal examiner is familiar with the type of graduate who knows all about the constitution of the atom but cannot read a vernier scale or perform simple exercises in mensuration. "Industry", he said, "wants physicists who have some idea how thick a piece of copper wire has to be to carry a hundred amperes."

The Planning Committee of the Institute of Physics, of which Sir Lawrence is chairman, is examining the whole question of the training of physicists after the War, although rightly, at present, many of its meetings were concerned rather with the present training and supply of physicists. Having in mind the Government's declared policy of devoting attention to post-war planning and especially to that part concerned with our export trade, the Board of the Institute has instructed the Planning Committee to examine the position of physicists after the War. A memorandum on training has, therefore, been prepared with the view of provoking open discussion, and copies of it will be available to non-members of the Institute on request. Sir Lawrence urged the constant interchange of physics students and staff from the universities with corresponding personnel from industrial and Government laboratories and made some concrete suggestions for the realization of this project. The Institute of Physics in co-operation with other scientific and engineering institutions has certain of these and similar proposals under examination. Physics will have to play an ever-increasing part in both our old-established and newer industries if they are to be enabled to compete fairly in the world's markets after the War. The Institute must, therefore, give the lead in seeing that Great Britain has a sufficient number of adequately trained and able physicists to meet the requirements of industrial and Government undertakings.

A Liquefaction Plant for Natural Gas

The city of Cleveland, on the south shore of Lake Erie, has a population of more than 1,200,000. For domestic purposes and many industries, natural gas is supplied by the East Ohio Gas Co., the gas being brought to Cleveland through four pipe-lines from Hastings, West Virginia, about 150 miles distant. In the early part of each year, short spells of extremely cold weather are experienced, and during these spells there is a great increase in gas consumption. To meet these exceptional demands a liquefaction and storage plant has been erected possessing many interesting features. A description of the plant and a diagram of the processes involved are given in the *Engineer* of May 22. The natural gas is first freed from moisture, carbon dioxide and nitrogen, and then by means of refrigerators the gas is liquefied and its temperature reduced to −258° F., at which temperature it is stored in three insulated spherical tanks under a pressure of 10 lb. A tank consists of an inner sphere of stainless steel 54 ft. in diameter, and an outer sphere of mild steel 60 ft. in diameter. The intervening space is filled with cork through which dried gases are passed to absorb moisture. The total amount of liquid gas stored in the three tanks is equal to the amount of free gas which could be contained in fifty ordinary gas holders each having a capacity of 3,000,000 cub. ft.

Institute of Physics

The annual report of the Board of the Institute of Physics which was adopted at the general meeting held on May 28 records the continued growth in numbers and activities of the Institute. One of the features of the year was the formation of the Industrial Radiology Group—the first subject Group to be formed—under the auspices of the Institute. This step has already been followed by the formation of an Electronics Group. The following were elected to take office on October 1, 1942: *President*, Sir Lawrence Bragg; *Vice-Presidents*, Dr. W. Makower and Mr. T. Smith; *Honorary Treasurer*, Major C. E. S. Phillips; *Honorary Secretary*, Prof. J. A. Crowther; *Ordinary Members of the Board*, Prof. J. Chadwick, Prof. J. D. Cockcroft, Mr. D. C. Gall and Mr. E. B. Wedmore.

Newton Tercentenary Celebrations

The Royal Society will, if circumstances permit, celebrate, at its anniversary meeting on November 30, the tercentenary of the birth of Sir Isaac Newton. The programme, which will be a modest one owing to the War, is to include three lectures, to be delivered in the Society's apartments at Burlington House, Piccadilly, on "Newton and the Science of his Age", by Prof. E. N. da C. Andrade, Quain professor of physics in the University of London; "Newton as an Experimenter" (with demonstrations), by Lord Rayleigh, emeritus professor of physics in the Imperial College of Science and Technology; and "Newton and the Science of To-day", by Sir James Jeans, professor of astronomy in the Royal Institution of Great Britain.

Storage of National Wheatmeal

A report on the problem of the storage qualities of National wheatmeal has been published by the Research Association of British Flour-Millers in *Milling* of May 23. Storage trials were carried out over a period of a year and included not only laboratory experiments but also tests under commercial conditions in mills, bakeries and buffer depots. Moisture content is the most important factor determining storage life: thus at 14, 14½ and 15½ per cent moisture contents, provided the storage conditions are good and a sound wheat grist is used, the wheatmeals will keep in good condition for 9 months, 4–6 months and 2 months respectively. Temperature is a further factor, and whereas at 60° F. a wheatmeal of 15½ per cent moisture remained in good condition for 11 weeks, at 77° F. it kept only for 3–4 weeks. An additional point of importance revealed by the experiments is that National wheat meal is more prone to insect infestation than white flour.

Silver Leaf Disease

Silver leaf is one of the most serious diseases with which fruit growers have to contend, and the Advisory Leaflet No. 246 issued by the Ministry of Agriculture should do much to clear up misunderstandings on the nature of the disease and thereby improve the methods of control. *Stereum purpureum* is a parasitic fungus which attacks the living tissues of the wood by means of wound penetration. It does not occur in the foliage, and the silvering of the leaves is merely a secondary effect of the attack. Discoloration and eventual death of the infected woody parts of the tree occur, followed by the development of fruiting bodies, by means of which the disease is spread. Illustrations of these fructifications are given, for their recognition on dying trees, old stumps or logs is important if adequate control of the disease is to be obtained.

The silvered leaves do not constitute a source from which the disease can spread. Natural recovery is always a possibility in a slightly affected tree, and removal of all silvered branches in the early stages may prevent an extension of the trouble. Branches that have begun to die back, however, must be cut out and burnt early in the summer and no stumps or roots of a dead tree left in the ground. Every effort should be made to prevent and protect natural wounds on the trees, as it is at such surfaces that the parasite gains an entry. Many kinds of fruit trees may be attacked by this disease, but plums are particularly susceptible, though the variety, or the stock on which the variety is grafted, may influence the susceptibility to some extent. A list of the more commonly attacked varieties of plum and apple is given.

Carnegie United Kingdom Trust

The twenty-eighth annual report of the Carnegie United Kingdom Trust (Dumfermline: The Trust) covers the year 1941, and for reasons of economy omits the accounts from the general distribution although they can be obtained on application. Considerations which govern the grant policy of the trustees are detailed in an appendix. The two main policies upon which the Trust is now engaged, operating on a year-to-year basis, are youth service and music. In regard to the former, grants have been offered to local voluntary bodies in aid of capital expenditure on the equipment of clubs for young people, including both the initial equipment of new clubs and the provision of additional equipment for existing ones. Contributions have also been made to the headquarters administration of the National Associations of Boys' Clubs, Girls' Clubs and Young Farmers' Clubs in England and Wales and in Scotland. Publication of the full report on the exploratory work on mixed clubs for young people of both sexes is anticipated early this year. Grants have also been made for the training of potential youth leaders, but the experiment with youth service camps in Oxfordshire has proved unsuccessful and has been discontinued. The Music Education Committee is encouraging the establishment throughout England and Wales of county music committees to co-ordinate all amateur musical activities in the administrative county areas and to foster new developments. The joint Committee for Drama seeks to promote the establishment of county drama committees and the appointment of county drama organizers. Contributions to the Land Settlement Association have been considerably reduced, but grants to the National Council of Social Service have continued at the £5,000 level in 1940–41–42. In addition, a grant of £3000 to the Y.M.C.A. has enabled the Association to continue its scheme of training boys for farm work and placing them in permanent positions on the land; more than six hundred boys were successfully trained and placed during 1941.

New Zealand Earthquakes

ACCORDING to a bulletin just received from the Dominion Observatory, Wellington, twelve strong earthquakes were registered during February 1942 by the thirteen seismographic stations in New Zealand. The interpretation of many of the seismograms was hindered by microseisms, though it is thought that the earthquake of February 17, the preliminary waves from which arrived at Wellington at 04h. 18m. 24s. U.T., had its epicentre in the Coral Sea. A good deal of minor activity, which is expected in New Zealand, was recorded, and many local shocks were reported as having been felt by observers throughout the islands. The highest intensity reached was 6 on the Rossi-Forel scale (ringing of bells, stopping of clocks, breaking of windows, etc.), which occurred on two occasions: on February 21 at 22h. 23·9m. U.T., felt at New Plymouth, and on February 22 at 12h. 18·1m. U.T., felt at Whakatane and Opotiki, and followed by numerous minor shocks.

Earthquakes Registered in Switzerland

FROM October 1, 1941, until January 31, 1942 (bulletins just received from Zurich), fifty strong earthquakes were registered by the seismographs at Chur, Basel, Neuchâtel and Zurich. Some of these earthquakes were local (that is, in Switzerland), and others have been noticed previously in NATURE. Two, which have not been mentioned previously, occurred in Italy. They were on November 10, 1941, with epicentre near Lago di Garda, *eP* being registered at Chur at 03h. 29m. 21·8s. U.T., and on January 2, 1942, with epicentre in the neighbourhood of Trento, *eP* being recorded at Zurich at 09h. 00m. 41·2s. U.T.

Leprosy in Brazil

ACCORDING to the *Journal of the American Medical Association* of April 4 the prevalence of leprosy in Brazil is comparable to that of the U.S.S.R., which has about 170,000 lepers to 170 millions of population. There are now sixteen modern leprosariums, where 15,173 patients were isolated on December 31, 1941. In the State of São Paulo more than 90 per cent of the contagious cases are isolated in six leprosariums, about 2,500 cases are isolated in the State of Minas Gerais and about 1,000 in the State of Para. There are 15 preventoriums where the healthy children of lepers are interned and many more institutions of the kind are being organized. Since 1938 the technique of infiltrations of the lesions through multiple local injections of chaulmoogra oil has been increasingly used with good results. The epidemiology of leprosy in Brazil is now being investigated. About 25 per cent of the cases are of the purely nervous form. The disease is more prevalent in males than in females and in coloured natives than in white Brazilians. The prevalence is also higher in white foreign people and in white foreign-born Brazilians than in white native-born Brazilians.

University College, Exeter: Air-raid Damage

DURING recent air attacks on Exeter, certain parts of University College were damaged. Some damage was done to the Botany Laboratories, the office building and the Handicraft Centre were completely burnt out, considerable damage was done to the new Library and two halls of residence. All the glass-houses, potting sheds, storehouses, etc., on the College estate were destroyed.

Comet Grigg-Skjellerup

A TELEGRAM from Tokyo has been transmitted by Strömgren announcing the discovery of this comet by Kanna Sekituti. Its position on May 9d. 11h. U.T. was R.A. 7h. 10m., Dec. 11° 46′ N. The magnitude is given as 10.

In the "Handbook of the British Astronomical Association", 1942, Mr. F. R. Cripps has provided the elements and an ephemeris for this comet. The position is very close to that given in the "Handbook", and the object can be easily found from the ephemeris without any corrections.

Date	R.A.	Dec.	r	ρ
June 10·0	9h. 48·6m.	+31° 53′·8	0·899	0·370
18	11 02·5	38 12·4	0·944	0·338

Announcements

AT the anniversary meeting of the Linnean Society of London held on May 28, the following were elected officers for the year 1942–43: *President*, Dr. E. S. Russell; *Treasurer*, Major F. C. Stern; *Deputy Treasurer*, Dr. B. Barnes; *Secretaries*, Mr. I. H. Burkill (botany) and Dr. Malcolm Smith (zoology). The new members of Council are Dr. G. S. Carter, Dr. F. C. Fraser, Mr. C. C. Hentschel, Dr. N. A. Mackintosh and Dr. R. Melville.

THE National Institute of Hygiene, which was recently founded in Paris, will consist of four departments devoted respectively to epidemiology, general hygiene, problems of nutrition and social diseases (cancer, syphilis, tuberculosis and alcoholism). Each department will be provided with laboratories. The institute will be under the authority of the State Secretary for Family and Health. A National Institute for Social Insurance has also been founded in Paris and will be under the authority of the State Secretary of Labour.

LETTERS TO THE EDITORS

The Editors do not hold themselves responsible for opinions expressed by their correspondents. No notice is taken of anonymous communications.

Origins of Human Graphic Art

The following incident deserves scientific record, both for its intrinsic interest and for its bearing on the possible origins of human graphic art.

Meng, a young mountain gorilla (*Gorilla g. beringeri*), previously in the Zoological Society's collection at Regent's Park, was kept in a cage with white tiled walls, illuminated by a single powerful electric light. When he stood in a certain position close to the wall, the light cast a well-defined shadow of the animal on to the white surface. I was watching him one day in February 1939, when he was approximately one and a half years old. Seeing his shadow before him at one moment, he stopped, looked at it, and proceeded to trace its outline with his forefinger.

Luckily, there was an independent scientific witness of this act, as I was accompanied by Mr. E. B. Ford of Oxford. He also had noticed the gorilla's action, and agreed that it was clearly deliberate. The animal proceeded to repeat the same action twice more, but then went on with his play.

I later arranged for a small projection lantern to be set up in the cage so that shadows of different shape could be thrown on the wall. However, the gorilla refused to take any interest, and was never seen to repeat the original performance before his death at the age of about three years. I should add that Meng was exceptionally intelligent and docile.

I can find no record in the literature of any anthropoid performing a similar action. It would be of considerable interest if observation and experiment designed to elicit similar behaviour were carried out on other young anthropoids.

Various suggestions have been made as to the origins of human graphic art: for example, scribbling, the incision of geometrical patterns or their tracing in sand or clay, tracing the outline of a hand or other object held against a rock face, as well as deliberate attempts at representation. To these I think we should add the possibility of tracing the shadows cast by a low sun against a more or less vertical cliff or cave-wall.

Effect of Ascorbic Acid on the Survival of Traumatized Animals

Clinical observers seem to be generally agreed that there is little relation between the degree of traumatic shock and the severity of the injury by which it is produced. However, the following observations, made during the course of a general study of wound ballistics, suggest that there is a quantitative relation between shock and trauma, even though there may remain some doubt how far the traumatic shock seen in experimental animals is equivalent to the clinical condition of 'shock' observed in man.

The primary purpose of these observations was to relate the degree of trauma, expressed in terms of the energy by which it is caused (all other conditions being kept constant) and the severity of 'shock' as estimated by the mortality-rate in groups of anæsthetized animals traumatized to different degrees. Thus, in a first series of experiments with anæsthetized guinea pigs, it was possible to calculate the amount of energy transmitted to the tissues by the missile by which they were injured. It was found that the amount of energy is related both to the degree of tissue damage and to the mortality-rate.

In a second series of experiments, anæsthetized guinea pigs were traumatized by means of a weight falling from different heights. It was again found that there is a definite relation between the mortality-rate and the amount of transmitted energy. Thus, death practically never occurs when the energy of the blow is less than 2·75 kgm. m. It occurs more frequently at energy levels between 2·8 and 3·4 kgm. m., and appears to be constant at a level of 3·7 kgm. m. Post-mortem examination of the animals used in these experiments showed the typical hæmorrhagic lesions which are stated to be characteristic of shock (Moon, 1938)[1].

If it be assumed that the condition of the animals during the post-traumatic interval is equivalent to that which is clinically recognized as 'shock', these experiments suggest that there is a quantitative relationship between the intensity of shock and the chances of survival on one hand, and the degree of trauma administered on the other. A similar conclusion is suggested by Noble and Collip (1942)[2] in a paper which has just appeared.

A further series of experiments has been carried out in order to test the effect of ascorbic acid on the survival of guinea pigs injured by a falling weight. It was found that animals subjected to the minimum degree of traumatization which otherwise would have caused 100 per cent mortality always survived after the subcutaneous injection of ascorbic acid, in doses above 100 mgm./kgm. body weight. The beneficial effect of the ascorbic acid becomes increasingly less if treatment is delayed after traumatization. Thus, if the injection of ascorbic acid is made after the lapse of an hour, survival occurs in only some 50 per cent of the experimental animals. Following a suggestion by Dr. A. N. Drury, the influence of vitamin B_1, in doses of 5–15 mgm./kgm. body weight, was also tested. This substance was found to be less effective than ascorbic acid, only four of a group of ten traumatized animals given vitamin B_1 surviving.

The way in which ascorbic acid exercises its effect in these circumstances is unknown. Guinea pigs, like man, do not synthesize their own ascorbic acid, but obtain the vitamin from their food. All the guinea pigs used in these experiments were maintained on the same diet, but, since no vitamin C estimations were performed, it is not impossible that some of them were deficient in this factor. Whether or not this was the case, the experiments suggest that the administration of ascorbic acid in doses higher than the normal vitamin requirement has a very marked effect upon survival. The possibility that the effect is due to some pharmacological property not encompassed by the term 'vitamin' was tested in a further set of experiments on rats, which were also traumatized by means of the falling weight technique. As in the case of guinea pigs, it was found that rats which were traumatized at a level of energy-input at which control experiment showed that death would normally ensue, survived if given ascorbic acid, shortly after the trauma, in a concentration of 100 mgm./kgm. body weight. Since rats synthesize their own ascorbic acid and are animals in which, by definition, ascorbic acid is not a vitamin, it is probable that the beneficial effect of the substance after trauma is due to some other pharmacological property, which it possesses.

The above experiments, of which a full account will be published later, are part of a programme of work on wound ballistics carried out under the direction of Dr. S. Zuckerman.

A New Synthesis of X-Ray Data for Crystal Analysis

RECENTLY considerable discussion has taken place about the use of Patterson vector diagrams in crystal analysis[1]. The difficulties of interpreting these diagrams in the case of complex structures as pointed out in this discussion and particularly emphasized by Sir Lawrence Bragg have led me to develop a more efficient method. This seems to be possible in the following way. Imagine a linear crystal consisting in its unit interval of s dimensionless atoms of atomic number Z_α and parameter x_α ($\alpha = 1, 2, \ldots s$). Then we can define a quantity $E(h)$ deducible directly from X-ray intensity data by

$$E(h) = \sum_{\gamma=0}^{t} g_\gamma \cos 2\pi h u_\gamma, \quad . \quad . \quad . \quad . \quad . \quad (1)$$

where $g_0 = \frac{1}{2} \sum_{\alpha=1}^{s} Z_\alpha^2$, $g_\gamma = Z_\alpha Z_\beta$, $t = s\,(s-1)$, $u_\gamma =$ $x_\alpha - x_\beta$ or $1 - (x_\alpha - x_\beta)$ according as $x_\alpha - x_\beta <$ or $> \frac{1}{2}$ respectively. My principal idea in the new method is to synthesize the empirically deduced $E(h)$ according to equat. (5) given later in such a way that $E(h)$ is put empirically into the form :

$$E(h) = \sum_{\mu=0}^{N/2} P_\mu \cos 2\pi h u_\mu, \quad . \quad . \quad . \quad . \quad . \quad (2)$$

where N is the number of divisions into which the fundamental unit interval of the linear crystal is divided. The possibility of the empirical determination of equat. (2) rests on the discovery of the equation,

$$E(q) = \frac{q \sin \pi q}{\pi} \sum_{h=0}^{\infty} (-1)^h \frac{E_h}{q^2 - h^2}, \quad . \quad . \quad (3)$$

where h is zero or an integer and q any real number; $E_0 = E(0)$, $E_h = 2E(h)$. Equat. (2) is then established by a suitable method of Fourier expansion of $E(q)$ given by equat. (3). The final formula for the calculation of P_μ is,

$$P_\mu = \sum_{h=0}^{\infty} a_{\mu h} E_h, \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (4)$$

in which $a_{\mu h}$'s are constants depending on N and independent of the structure investigated. $a_{\mu h}$ decreases with h so that the right-hand side of equat. (4) is a convergent series. The linear relationship between P_μ and E_h enables P_μ to be computed quickly by a computing machine or by means of strips similar to those devised by Beevers and Lipson[2] for the computation of Fourier summation.

It is to be noted that equations (1) and (2) are of the same form. If N is chosen large enough, equations (1) and (2) would be almost identical term by term. Consequently, a comparison of the empirically determined P_μ with the theoretically calculated g_γ gives us information not only of the numerical values of u_γ but also of which pair of atoms this u_γ is due to. Furthermore, since Z's are known integers, the identification mentioned above is possible even when the values of P_μ determined empirically are not exactly equal to those of g_γ. This may arise from an incorrect choice of N, from the approximation introduced in equat. (5) mentioned below, or from the experimental error within the limit of modern intensity measurement. The choice of N is guided by the accuracy of intensity measurement, the complexity of the structure investigated, and the number of atoms contained in the unit interval. If necessary, the question whether N has been chosen correctly or not can be settled by making various syntheses for different values of N, say, N, $N/2$, $N/4$ to see if some of the equivalent terms in equat. (2) shift or not, or the values of some P_μ suffer a great change. In this way more exact and more definite information can be obtained.

$E(h)$ defined by equat. (1) is deduced from the observed $|F(h)|^2$ values of the actual structure by

$$E(h) = \frac{|F(h)|^2 8}{2\psi(j)^2}, \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (5)$$

where $\psi(j)$ is the well-known function involved in the calculation of atomic structure factor f by the Thomas-Fermi method[3]. Numerical values of $\psi(j)$ for j ranging from 0 to $3{\cdot}85\pi$ are available[4]. Equat. (5) is exact if the structure investigated is one of a pure element or an alloy in a disordered arrangement. When the structure contains no comparatively heavy atoms, equat. (5) is still almost exact; otherwise it is true only to a near approximation. But in the last case only those terms in equations (1) and (2) which involve the contributions of the heavy atoms stand out, and therefore an identification of these terms alone is sufficient for an analysis. We thus expect the method to be applicable to all cases.

Finally, we may construct a point diagram in the one-dimensional discontinuous μ space in which every point μ is associated with a corresponding P_μ according to equat. (2). The result is similar to the Patterson vector diagram, with the following differences :

(1) The quantity marked on the diagram is $Z_\alpha Z_\beta$. Thus the nature of the vectors is known at once.

(2) The diagram is a point diagram so that there is, theoretically speaking, no fear of interference of peaks provided the unit interval is finely divided. If superposition between peaks takes place, this superposition will be known directly from the comparison $P_\mu = g_\gamma$; otherwise the peaks should remain distinct from each other, no matter how close they crowd together. The last statement means that the method is applicable to complex as well as simple structures. The sharpening of peaks is partially successful in the modified Patterson method[5]. But

there the gain in resolving power is at the expense of the truthfulness of the background of the diagram by the introduction of undesirable spurious peaks.

(3) Since the series in equation (4) is convergent, it can be cut off at a suitable high order term without appreciable effect on the calculated values of P_μ. Thus, in contrast with all the Fourier methods, the so-called diffraction effects should be theoretically inappreciable in the new method.

In view of these significant improvements, we conclude that the new synthesis will be able to derive more useful information directly from the observed data than the classical Patterson, and so further narrow down the choice of alternative structures in an actual analysis.

I cannot enter here into many points which are essential for the complete understanding of the method. A detailed account, including the extension to two and three dimensions and the generalization of the method to other classical Fourier methods, will be given elsewhere. The calculation of $a_{\mu h}$'s of a two-dimensional synthesis for $N = 100$ is being undertaken. As a preliminary study and as an illustration, the method has been applied to the analysis of the simple known structure of iron pyrites. The result has been briefly described in *Science Records*[6].

Enzymatic Production of Bacterial Polysaccharides

SEVERAL investigators have reported the formation of polysaccharide material by sterile filtrates obtained from various species of spore-forming bacilli. Thus in 1910 Beijerinck[1], using 'viscosaccharase', an enzyme present in filtered preparations of *B. mesentericus*, observed the formation of 'slime' on a sucrose-agar medium. In 1930 Harrison *et al.*[2] isolated this enzyme and showed that the 'slime' was a levan. Dienes[3], working with Oerskov's milk-bacillus and with organisms of the *subtilis* group, demonstrated that sterile extracts of these organisms could form from sucrose 'extra-bacterial' granules of a polysaccharide nature. He, too, was probably dealing with a levan-synthesizing enzyme which has now been isolated in an active form from Aerobacter[4].

From *Leuconostoc mesenteroides* Heyre and Sugg[5] isolated in an ingenious manner an enzyme which could synthesize, from sucrose alone, a dextran identical both chemically and serologically with the dextran produced by the living organism. Some time ago in these laboratories we also isolated an extremely active exocellular dextran-synthesizing enzyme from *L. mesenteroides*, but circumstances caused the interruption of the work before our investigations were completed. Inasmuch as we hope to resume the research at some future date we now publish our preliminary results, which initiate a new field of study concerning the symbiosis of yeasts and bacteria.

Our investigations[6] dealt with the search for growth-promoting factors which could stimulate dextran production by Leuconostoc species. We obtained a number of 'slimes' from a beet-sugar factory, and one of these was subjected to bacteriological analysis by Prof. A. J. Kluyver of Delft and was found to contain *L. mesenteroides*, *Saccharomyces cerevisiœ* Hansen and a Streptobacterium, each of which he isolated in pure culture. Since many natural viscous fermentations, such as Kephir and Tibi[7], are due to the symbiotic action of yeasts and bacteria, it occurred to us to grow this strain of *L. mesenteroides* in symbiotic association with *Saccharomyces cerevisiœ*. The growth medium was that described by Stacey and Youd[6] and 5 c.c. quantities were inoculated separately with the yeast and the Leuconostoc and incubated at 30°. After two successive subcultures from the mixed culture there was a remarkable production of dextran, the yield reaching a maximum in forty hours, whereas a period of ten days was required by the *L. mesenteroides* in pure culture to produce its maximum yield. After a third successive subculture it was noted that an opalescence occurred in the medium after one hour, that there was considerable dextran production after four hours, while after ten hours the whole medium formed a gel composed almost entirely of dextran. In the four-hour culture above, microscopic and cultural examination revealed the almost complete absence of both yeasts and bacteria, so that dextran production at this stage was undoubtedly due to exocellular enzymatic action. Confirmation of this was forthcoming from the fact that heavy inoculations from sterile filtrates of twenty-four-hour cultures produced dextran in a few hours on the same sucrose-peptone medium. This production was, however, less dramatic than that obtained by inoculation with an equal amount of unfiltered ten-hour cultures, and there is little doubt that in the latter case the enzyme system was sharply stimulated by a factor elaborated *in situ* by the living yeast cells.

The dextran was of the mucoid type and, after isolation, remained insoluble in water. By the method described by Daker and Stacey[8] it was obtained in a less viscous, water-soluble form, $[\alpha]_D + 180°$ in water, N, 0·5 per cent, and gave only glucose on acid hydrolysis.

The isolation of an enzyme capable of synthesizing a polyglucose having 1 : 6-linkages[9] from sucrose (glucose-1-fructofuranose) would appear to have a significance comparable with Hanes's discovery of the starch-synthesizing enzyme which utilizes glucose 1-phosphate; and further work in this field should lead to an understanding of some of the underlying mechanisms of enzymatic synthesis.

Simplification of Musical Notation

The value of the scientific method, to which Lord Brabazon appeals, lies in the proper use of experiment. There is available to-day a growing amount of piano music which is written without key signature, because it is without key, and with chromatic notes inserted as required. It is easy to find out whether it has the advantages Lord Brabazon assumes for his tentative proposal to omit key signatures as a first step towards a simpler notation.

For my own part I find this music difficult to read, because I have then to read each note. That may be one reason why such music repels me. But for earlier music, for which staff notation was developed, Lord Brabazon's analogy with the printed book is a good one. Just as one does not read each letter, perhaps not even each word, of a printed sentence (whence the difficulty of proof correction), so in reading music one has no time to read each note. One reads groups of notes.

Such proposed alternatives for staff notation as I have seen do not readily assist this kind of reading. In other words, they hold no promise of standing up to the scientific test, that of the control experiment. Until someone invents a notation that does, which will make music in twelve-tone technique easier to read, and perhaps to understand, musicians will remain hopeful but not expectant.

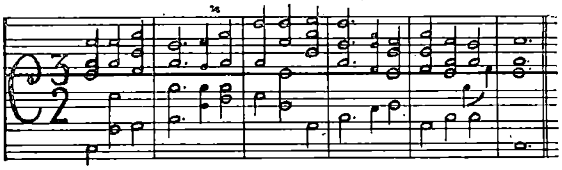
Ll. S. Lloyd.

Department of Scientific and
Industrial Research,
Teddington, Middlesex.

The plea of Lord Brabazon in Nature of May 16, p. 554, will be strongly supported by thousands of would-be players to whom the complications of clefs, key changes and accidentals have proved an impassable barrier, and by the parents of many otherwise musical children who have given up their pianoforte studies in despair because of these difficulties. On the plea of the greatest good for the greatest number, therefore, Lord Brabazon's appeal ought to receive most careful and unbiased consideration, and not least from those musicians whose real desire it is to extend the art of music-making among ordinary people. Furthermore, the use of a special form of stave for the piano and organ would not be so great a departure from tradition as might at first be supposed, for is it not on a par with the provision of special clefs for some of the instruments in the orchestra ? (Incidentally, why must we continue to use an *H* to denote a *C* clef, and a *C* for an *F* clef ?)

As a practical contribution may I put forward a simple solution ? Why not make the appearance of the printed music bear an easily recognized resemblance to the array of black and white keys on the keyboard ? Thus : make the stave consist of horizontal lines in sets of twos and threes, so that the *black lines* correspond to the *black keys*, and the white spaces the white keys. This would do away with the "treble" and "bass" clefs, with their different names for similarly placed symbols, and eliminate all sharps and flats. The three octaves at present included within the compass of the normal treble and bass clefs would naturally occupy a little more space, but the gain in clarity is obvious; every note on the keyboard having its unmistakable and unique position on the printed page.

The following example shows the first six bars of the National Anthem in the key of *A* (3 sharps) written in the new notation*. The 'dot' forming the commencement of the "C" at the beginning of the stave represents the middle *C* of the piano.



The line denoting middle C sharp is purposely made bolder ; this guides the eye and improves clarity.

Leger lines, with similar gaps between the groups of twos and threes, would be employed for notes above and below the stave, but the use of the (8ve) and (16ve) devices is to be strongly recommended wherever possible.

If any music publisher should be sufficiently interested and large-minded to answer Lord Brabazon's plea by preparing to issue a series of graded classical and popular music in some such simplified notation, as soon as war-time restrictions are relaxed, he would earn the gratitude of many now living who are debarred from 'making their own music' by the barbed-wire entanglements of sharps and flats, and would bring into the realm of possibility for future generations an era of 'music without tears'.

* Since devising this stave I have found that one on similar lines was put forward some 50 or 60 years ago by Mitcherd. Evidently then the times were not propitious !

Luminous Phenomenon Accompanying the Cyprus Earthquake, January 20, 1941

As reported in Nature of February 1 and 8, 1941, an earthquake of intensity VII or VIII on the Forel-Mercalli scale—the severest in Cyprus for the last sixty years—occurred on January 20, 1941, at about 5.35 local time. The beginning, as recorded at Ksara Observatory near Beyrouth, was 3h. 37m. 38s. G.M.T.

The epicentre lies between Cyprus and the Syrian coast, 200 km. from the latter and probably near the south-east coast of Cyprus. This is a region where earthquakes are not very rare.

A bright flash associated with the earthquake was seen from the eastern and central parts of the island. A Nicosia Hodja who was on the minaret for morning prayer, in describing the event, said that he first heard a deafening noise suggesting the impact of a gigantic projectile on the surface of the earth with a simultaneous rocking motion so severe that he feared the minaret would collapse. Afterwards he saw a brilliant reddish object like a huge globular lightning moving slowly towards the east. The tremors then changed into horizontal waves and gradually vanished. There is strong evidence that direction of the flash was pointing to the epicentral area.

RESEARCH ITEMS

Modern Stone-Age Man in South Australia

AN interesting light is thrown on possible methods used by early man by a recent description of modern stone-age man in the Musgrave Range, South Australia. The Pitjendara tribe is one of the most primitive in Australia, and among their few possessions are spears and spear-throwers fitted with an adze stone on the end. The manufacture of these spear-throwers is the subject of a recent paper "An Unrecorded Method of Manufacturing Wooden Implements by Simple Stone Tools", by C. P. Mountford (*Trans. Roy. Soc. South Aust.*, 65, (2); 1941). The tools selected were natural stones chosen for possible cutting edges, but left undressed. With these as the sole instruments a shaped slab of wood was stripped from a small mulga tree—a slow, laborious process—and the bark removed before being taken to camp. Here the shaping and finishing took place with the help of smaller, but still unflaked, stones, and finally with the aid of the adze stone of a finished spear-thrower. The adze stones themselves were merely flakes of chert with good cutting edges and were stuck into the handle end of the spear-thrower with spinifex gum warmed over the fire. When these stones became blunted with use there were some attempts to create a fresh cutting edge by tapping them with the wooden blade of a spear till miniature flakes were broken off. The throwing peg was made of wood and attached by spinifex gum to the tip of the spear-thrower and then securely bound with tendon. The stones used in these processes were all discarded and left behind, and as such stones bear no recognizable trace of their use by human beings, a material culture such as that of the Pitjendara tribe might well become extinct without leaving any trace of its existence.

Hæmophilia-like Condition in Pigs

HÆMOPHILIA and blood conditions that resemble this abnormality have been known in man for many years. On the other hand, such a condition appears to have remained hitherto undetected among pigs. R. Bogart and M. E. Muhrer have described a hæmophilia-like condition in a line of inbred Poland China pigs (*J. Hered.*, 33, No. 2, 1942.) The feature first becomes evident at about two months in age but is by no means constant in this respect. In general, the abnormality becomes increasingly severe as the animals become older. Like hæmophilia in man, it is due to a thromboplastin deficiency. It appears that this hæmophilia-like condition in pigs is due to a recessive gene and that the variation between different individuals as regards the severity of the abnormality is brought about by modifying genes. The character is not sex-linked as in man but would cause great losses to pig breeders should the gene concerned become widespread. The authors observed the phenomenon in animals used for breeding at the Missouri Agricultural Experiment Station.

Colchicine and the Production of New Types of Forage Crops

UNTIL recently the production of improved varieties of plants has been almost restricted to selection and hybridization within and between closely related species, since intergeneric hybrids show a complete or high degree of sterility. Colchicine affects mitosis, and cells which have an optimum dose of this substance may begin to divide but fail to complete the process, so that the two sets of chromosomes reunite with a consequent doubling of the chromosome number. If this effect can be induced in tissues which will eventually give rise to the gametic tissues, normal pairing of chromosomes occurs at meiosis so that fertility is restored and an amphidiploid type is produced. The difficulty to date has been to devise a method of application of the colchicine which produces sufficient penetration of the tissues without killing the plant. F. H. Peto and G. A. Young (*Canadian J. Res.*, 20, No. 3, Sect. C; 1942) have tested methods of application of colchicine to sterile hybrids of Triticum species with *Agropyron glaucum*. The more effective methods were (1) immersion of the young seedling in 2 per cent colchicine solution and (2) enclosure of the decapitated seedling stem in a capsule containing agar with 0·1 or 0·4 per cent colchicine. The latter method affected the young tillers and proved the most effective; of the surviving plants 21·2 per cent showed fertility, and this treatment also led to less wastage of the valuable hybrid material than methods involving immersion of seedlings or seed in the solution. The application of these methods to Triticum-Agropyron hybrids shows that fertility may readily be induced in the sterile hybrids by doubling of the chromosome number; this opens the possibility of combining the characters of related genera and the production of a vast range of new types of forage crops. One such colchicine-induced fertile amphidiploid, first produced in 1938, is now available in sufficient quantity for extensive field tests, while a number of others will be ready for similar trials in the course of a few years.

Diseases of Miscellaneous Crops

SEVERAL uncommon diseases of seakale, artichoke, sweet corn, asparagus and rhubarb have been briefly described by D. E. Green (*J. Roy. Hort. Soc.*, 67, Pt. 3; March, 1942). Rhubarb is occasionally attacked by the honey fungus, *Armillaria mellea*, in addition to crown rot and grey mould. Seakale may be infected with club-root, black-rot (*Pseudomonas campestris*), soft-rot (*Bacterium carotovorum*) and violet root-rot (*Helicobasidium purpureum*), which also parasitizes chicory, artichoke and asparagus. Grain mould of sweet corn may be caused by several fungi of the genera Penicillium and Fusarium.

Analysis of Certain Foods

AT a meeting of the Society of Public Analysts and Other Analytical Chemists held on May 6, E. T. Illing and E. G. Whittle gave analytical data for samples of soya bean meal and of cereal fillers ('pabs' and bread) and discussed them in relation to the methods used. Starch was determined by several methods: precipitation by alchohol, and precipitation as iodo-compound which in some instances was decomposed and the starch precipitated by alcohol and weighed. Soya meal gave consistently high results by the first method, and moist mixtures of soya meal and bread gave low results by the last one. Methods were suggested for calculating the contents of soya meal, cereal and filler and meat in sausages and the like from the determined percentages of water, fat, protein, starch (by alcoholic precipitation) and salt-free ash. Some observations were made on the microscopic detection of soya.

Gravimetric Micro-determination of Magnesium

THIS method was described by P. F. Holt at a meeting of the Society of Public Analysts and Other Analytical Chemists on May 6. Benedetti-Pichler's method for the gravimetric micro-determination of magnesium, in which the metal is precipitated and weighed as $MgNH_4PO_46H_2O$, was found to give results which varied according to the time allowed for precipitation. Consistent but high results were obtained if the precipitate was allowed to stand in contact with the mother-liquor for several hours. A precipitation time of one hour or less gave values which were irregular but approximated to that calculated from the formula. Good values are obtained by this method if five hours are allowed for precipitation of the magnesium-ammonium salt and an empirical factor is used for conversion of precipitation weight to weight of magnesium.

Quantum Chemistry

THERE is a remarkable identity, due to Dirac, connecting the operators of exchange and spin. Taken in conjunction with the principle that in the problem of several electrons, a wave function must change sign when the orbital and spin co-ordinates are both subjected to the same permutation, the identity shows that any permutation of the orbital variables can be obtained from a certain spin operator. In other words, spin compensation goes with antisymmetry of the spin function. This is known to be fundamental in the quantum explanation of chemical bonds. E. Schrödinger has obtained a generalization of Dirac's identity (*Proc. Roy. Irish Acad.*, 47, 39; 1941). In the generalization, chemical compensation of spin occurs in groups of particles, instead of in pairs of single particles. Something like this applies to the heavy particles (proton-neutrons) in the nucleus. Spin compensation in this case corresponds to unit charge for each two particles. This view is supported by its agreement with several basic results concerning the nucleus.

Frequency Comparisons

L. A. MEACHAM (*Bell Lab. Rec.*, 20, No. 7, March 1942), in an article on high-precision frequency comparisons, describes a test circuit capable of making short time measurements. When measurements must be made within a short period, direct methods fail because the time intervals cannot be determined with sufficient accuracy; but as deviations rather than absolute values are of interest, it is possible to substitute comparisons between the frequencies of two or more similar but independent oscillators. Excellent precision is obtainable by this method with equipment built to check the performance of bridge-stabilized oscillators used in the Bell System frequency standard. The oscillators were designed to be stable within 0·0001 c./sec. and the testing circuit, therefore, had to detect a variation of ten times this amount. Furthermore, the momentary nature of the changes necessitates that the measurements represent nearly instantaneous frequency values and be obtained at very brief intervals. Two 100 kc. oscillators are employed, adjusted to differ in frequency by about 0·1 c./sec. Their outputs are added together in a hybrid coil and the sum amplified and rectified to fire a thyratron tube once each beat cycle, in turn discharging a condenser through a spark coil. The resulting high voltage from the coil causes a brief flash of light in the neck of a mercury vapour lamp. A circular scale marked in milliseconds is rotated by a 1,000-cycle motor synchronized with current from the frequency standard, to record the time between flashes. Each discharge illuminates the scale and records the time on a slowly moving film, so that the time which elapses during a single ten-second beat-cycle is recorded to the nearest thousandth of a second, and any irregularity in the beat frequency amounting to more than one part in ten thousand becomes apparent. As the frequency of the beat pulses is only one millionth of the frequency of either 100 kc. oscillator, the precision of the comparison between the pair of oscillators is approximately one part in ten thousand million (10^{10}). An irregularity so small as to be undetectable by any rapid direct method thus produces a very noticeable record in the new measuring device.

Penetrating Cosmic-Ray Showers

Counter experiments on showers penetrating at least 50 cm. of lead are reported by L. Jánossy (*Proc. Roy. Soc.*, A, 179, 361; 1942). It is concluded that these penetrating showers are parts of extensive air showers, are neither energetic cascades nor knock-on showers but are probably connected with the production of mesons. The connexion of the penetrating showers observed at sea-level with the production of mesons in the atmosphere is discussed from the alternate postulates that the mesons are (i) produced by photons and (ii) that they are mainly produced by protons and possibly neutrons.

Movements of Hydrogen Flocculi

M. A. ELLISON has described his investigations on surges near sunspots and quasi-eruptive flocculi in the vicinity of chromospheric eruptions (*Mon. Not. Roy. Astro. Soc.*, 102, 1; 1942). A short account is given of the spectrohelioscope which was used at Sherborne (*J. Brit. Astro. Assoc.*, 50, 107; 1940) but some modifications were introduced for the present investigation. Ellison has kept a special watch for surges since 1940 and has found that they are the most frequent of all prominence types, though they are the most short-lived of chromospheric phenomena. Radial velocity - time curves are shown in diagrams and a table includes various details regarding position, times of beginning and ending, etc. Distance integrals and accelerations are deduced and the former are in satisfactory agreement with the heights observed for the limb prominences of corresponding type. In the case of quasi-eruptive flocculi, the Doppler time-curves are of the same general form as those for surges, but the velocities of ascent and descent are greater. In one case the velocity of ascent was found to be a little greater than the value of g on the sun's surface. In the years 1940–41 about five hundred measures of radial velocities were made on active short-lived dark flocculi which occurred in the vicinity of sunspots. A well-defined maximum frequency of descending motions was shown to exist at about 30 km./sec. and of ascending motions at 35 km./sec. These figures are in good agreement with those obtained by H. W. Newton at Greenwich in 1930–33. There is one important difference, however. The Greenwich analysis showed a high percentage of radial velocities in the range 0·9 km./sec., and the Sherborne results did not reveal this. The apparent discrepancy is due to the fact that Ellison sought specially for active flocculi and omitted slow-moving flocculi.

ing glide lamellæ is $2\,AB = 2t.\tan\varphi$, where t is the thickness of the lamellæ, and φ the angle between the glide plane and the normal to the plane of kinking. The condition that this should be an integral multiple of the lattice period a in the direction of glide is

$$2t.\tan\varphi = n.a.$$

This is the same phase relationship as that expressed by Bragg's law in the case of X-ray diffraction; $t/\cos\varphi = d$ is the spacing of the glide lamellæ in the plane of kinking. It is proposed to check this equation by X-ray measurements of the thickness of the glide lamellæ.

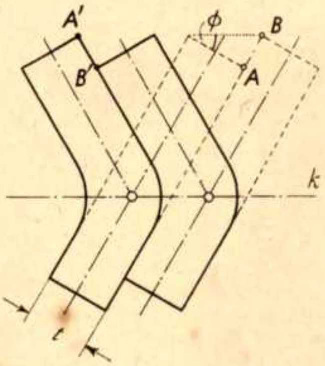

Fig. 4.
AMOUNT OF GLIDE BETWEEN NEIGHBOURING GLIDE LAMELLÆ.

Fig. 5 shows how plastic extension and compression may result from kink bands. In these diagrams the initial position of the glide planes was assumed to make angles of 45° with the stress axis, as is the case, for example, with sodium chloride crystals stressed in the (100) direction. If the angle φ is small, the angle between the kink band and the specimen axis is only slightly less than 45° in compression, and only slightly more than 45° in extension; thus in such cases the kink bands can easily be confused with genuine glide bands. Brilliantow and Obreimow[4] have shown that, in fact, the deformation bands in sodium chloride crystals compressed at room temperature represent not glide bands but what they called "irrational twins" or "big twins". While, for geometrical reasons, twins cannot be "irrational" in the sense used by these authors, it is clear from their description that at room temperature sodium chloride deforms mainly, or entirely, by kinking, and its well-known deformation bands are not glide bands but kink bands. There are many indications[5] that deformation bands in metals hitherto considered glide or twin bands may be, in reality, kink bands; and the possibility must be kept in mind that glide may begin in many or in all cases with kinking. The phenomenon of jerky extension[6] points in this direction.

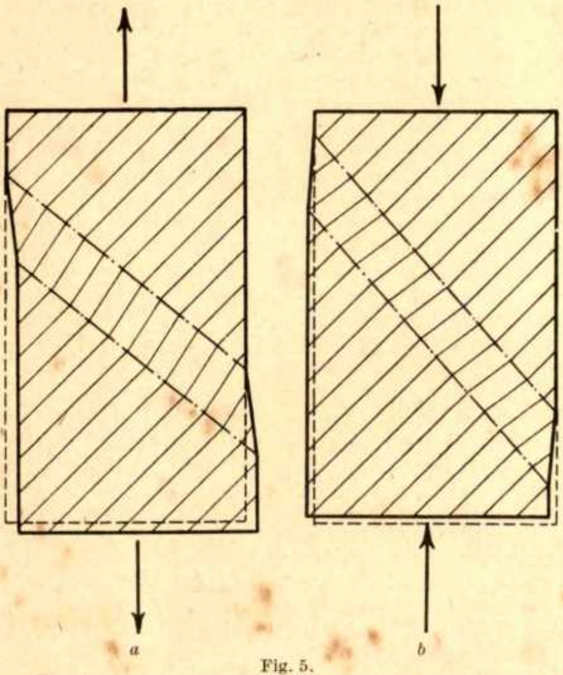

Fig. 5.
EXTENSION AND COMPRESSION OF A CRYSTAL PRODUCED BY KINK BANDS.
Thin parallel lines, glide planes.

It is known[7] that the angles between the Lueders bands in mild steel and the direction of stress are slightly less than 45° in compression, and slightly more than 45° in extension, in conformity with the behaviour of kink bands as shown in Fig. 5. Together with the sharp yield point observed in mild steel, this suggests that the deformation in mild steel may at least begin with kinking instead of glide or twinning.

Once a kink band has been formed, further deformation may take place either by glide across the band[5], or by gradual broadening of the band (displacement of the planes of kinking representing its boundaries). This latter type of deformation has actually been observed in cadmium crystals; its mechanism is identical with that theoretically postulated by Sir Lawrence Bragg some time ago[8]. In contrast with the familiar mechanism of deformation by glide packets sliding upon each other, the Bragg mechanism consists in a displacement of the boundaries between slightly differently oriented regions, such as represented by the original lattice on one hand, and the kink on the other.

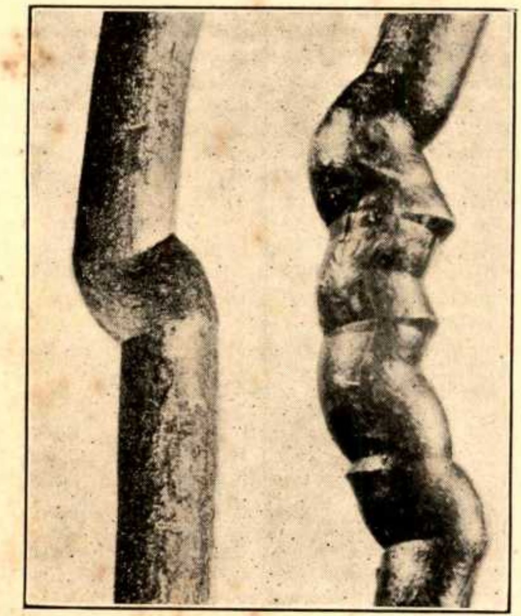
INDIAN FISHES AND MOSQUITO CONTROL

MUCH has already been written on the control of mosquitoes in India by introducing larvicidal fishes, and the researches of Hora and Nair resulted in successfully freeing the valve chambers of the Pulta Pumping Station of mosquito larvæ by introducing the killifish, *Aplocheilus panchax*. It was, however, still a vexed question as to whether this fish feeds preferably on mosquito larvæ in natural conditions. An interesting paper by T. J. Job[1], based on detailed experiments, shows that this fish is definitely of great practical utility in anti-mosquito campaigns. The efficiency of *Aplocheilus panchax* in

A TYPE OF PLASTIC DEFORMATION NEW IN METALS

By E. OROWAN
Cavendish Laboratory, Cambridge

SINGLE-CRYSTAL wires of zinc or cadmium, extremely soft in general, are as hard as polycrystalline wires if the glide plane (0001) is nearly parallel to the wire axis, so that the usual glide mechanism cannot work in extension or bending. In an attempt to operate the glide mechanism in cadmium crystals of such orientation, the crystals were axially compressed. As the load increased, they suddenly collapsed by forming peculiar kinks with sharp ridges and regular curvatures; the two main types of kinks are shown in Fig. 1. The regular curvatures, the non-crystallographic orientation of the planes determined by the ridges, and certain other features show that the phenomenon cannot represent ordinary glide or twinning.



a *b*

Fig. 1.
PHOTOGRAPHS OF KINKS IN ORIGINALLY CYLINDRICAL CADMIUM SINGLE-CRYSTAL WIRES OF 1 MM. DIAMETER.

A survey of the literature showed that kinks of perfectly similar shape were observed by Mügge[1] in crystals of disthene (cyanite) compressed parallel to their glide plane. Disthene being transparent, Mügge was able to determine the lattice orientation in the kinks by means of the polarizing microscope. According to his results, the structure of the kink in Fig. 1 *a*, for example, would be that shown in Fig. 2; this has been confirmed in the present case of cadmium crystals so far as is possible with X-ray methods. Beside regions with continuously bent glide lamellæ ("flexural glide"[2,3]), the deformed crystals contain planes *k*, *k'*, in which the glide lamellæ are so sharply bent that they appear broken; hence the sharp ridges and trenches shown for both specimens in Fig. 1. This characteristic part of the phenomenon is shown schematically in Fig. 3. Under the shear stress indicated by the horizontal arrows, a part of the crystal (that above the plane *k*) splits up into submicroscopic glide lamellæ of equal thickness which swing from the initial position shown by dotted lines to that drawn in full lines. The 'plane of kinking' *k* need not be a crystallographic plane; its orientation depends on the stress conditions. For geometrical reasons, the glide planes in the 'kink' (that is, the part above *k*) are mirror images of the glide planes in the undeformed part, with the plane *k* as a mirror. In contrast with twinning, however, the *lattice* in the kink is not a mirror image of the undeformed lattice: a lattice direction shown by the double-headed arrow in the undeformed part, for example, changes to the similarly marked direction in the kink.

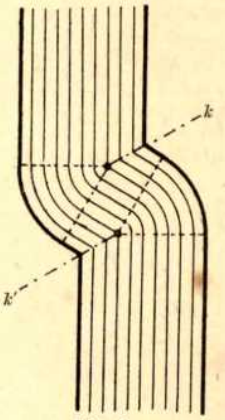


Fig. 2.
STRUCTURE OF THE KINK IN FIG. 1 *a*.
Thin parallel lines, glide planes. Broken lines, boundaries of the wedge-shaped regions of flexural glide. Dash-dotted lines *k* and *k'*: planes of kinking.

There is a characteristic difference between ordinary flexural glide and kinking. In flexural glide, the lattice constants at the compressed (concave) sides of the glide lamellæ differ from those at the extended (convex) sides; hence, the lattices of neighbouring lamellæ cannot fit upon each other, and dislocations between the lamellæ will be more or less evenly distributed over the region of flexural glide. In kinking, on the other hand, the glide lamellæ remain practically plane within a certain distance from the plane of kinking. As they swing over into their new position, they glide over each other like a row of books tilting to one side, and finally settle in a position in which the lattices of neighbouring lamellæ must be expected to fit upon each other correctly, while the dislocations are concentrated in the plane of kinking. In other words, the amount of glide between neighbouring lamellæ must be an integral multiple of the lattice period in the direction of glide. Fig. 4 shows that the amount of glide between neighbour-

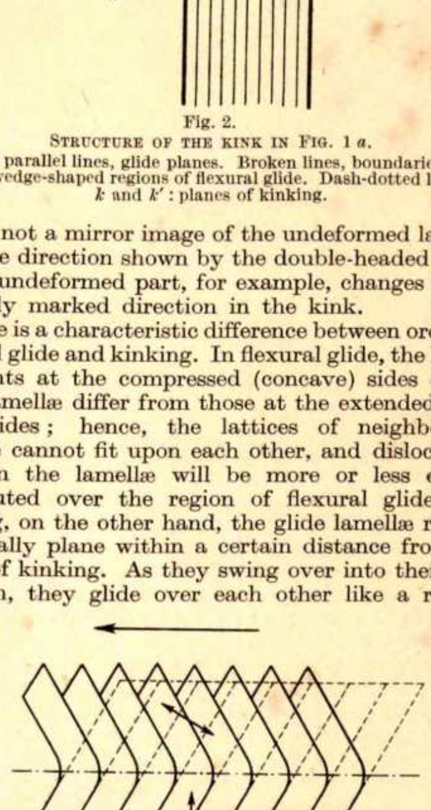

Fig. 3.
MECHANISM OF KINKING.

mosquito control has been studied by estimating: (*a*) the mosquito ratio in its diet, (*b*) the extent of check exercised by the fish in natural pieces of water, and (*c*) the effect, in the field, of introducing and of withdrawing the fish.

Food analyses of collections of fish from diverse natural habitats of rather low larval density, from observation chambers and pits of fairly high larval density, and from experimental aquaria with equal supplies of different food items, have revealed a decided preference for mosquito larvæ on the part of this fish. The author mentions the following attractive features of mosquito larvæ: convenient size, suitable pose of rest at the surface, enough mobility, absence of obnoxious exoskeleton, palatable nature and easy availability. All these must be factors which find favour with the fish.

Surveys of various types of natural water showed that whenever *Aplocheilus panchax* and mosquito larvæ occur in mutual association, and so long as the fish population is of an appreciable strength and the mechanical barriers, if any, are penetrable by the fish, the larvæ seldom thrive beyond the early instars. So far as *Aplocheilus panchax* is concerned, its efficiency for mosquito control, as proved from previous records and the present investigations, is fully established, and, being the most widely distributed and easily acclimatized of Indian killifishes, the practical possibilities of using it extensively in anti-mosquito campaigns is obvious.

The efficiency of the glassfishes (Ambassis) has also been estimated[2], and though they are less efficient than the killifish in control of malaria mosquitoes, their larvicidal activity is found to be of some significance. It is, however, in the control of the guinea-worm that the importance of Ambassis is shown, through their cyclopsidal habits. The intermediate host of the guinea-worm is known to be the copepod Cyclops or some closely related genus, and the glassfishes feed voraciously on these.

A third paper by the same author[3] deals with the bionomics of the spring eel, *Mastacembelus pancalus* (Hamilton), and shows that the number of mosquito larvæ in the gut contents is insignificant and that, "though to a small extent the fish may help to reduce the number of larvæ in marshy pools, it is not of any cognizable value in control of mosquitoes. Again . . . the proportion of *Cyclops* met with in the food of the species is too small to have any significance in the control of the Guinea-worm".

PROPERTIES OF RUBBER AT LOW TEMPERATURES

AN interesting account of the effect of low temperatures upon the properties of rubbers is given by M. L. Selker in an article entitled "Brittle Temperature of Rubber" (*Bell Lab. Rec.*, 20, No. 7; March, 1942). When crude rubber is held at about 14° F. (−10° C.) for some days, crystallization occurs and the rubber becomes stiff and opaque but remains elastic to some extent, permitting slight bending and stretching without breaking. Well-vulcanized rubber does not crystallize, but loses its ability to retract when stretched. Crude or elastic rubber, however, loses elasticity completely if cooled to 70–80° F. below zero. If bent suddenly at right angles a glass-like breakage occurs. This transition to brittleness occurs at a sharply defined temperature which differs for various natural and synthetic rubbers.

To study these brittle temperatures, the Bell Telephone Laboratories recently constructed a simple apparatus consisting of a quadrant (arranged to carry as many as six rubber specimens) mounted on a shaft turned by a simple crank, and supported in a narrow insulated tank into which acetone and 'dry ice', or other cooling solution, may be placed. The specimen to be tested is fastened to the quadrant and turned down into the solution sufficiently long for it to assume the bath temperature. A quick rotation of the crank then brings the specimen sharply up against a rigid metal bar projecting from the edge of the tank towards the rim of the quadrant. If the brittle temperature has not been reached, the specimen will bend, but otherwise it will break off cleanly.

It has been found that the rubber becomes so tough at these low temperatures that considerable force is required to break it. Tests carried out on natural and synthetic rubbers showed that the brittle point of soft vulcanized rubber, about − 75° F. (− 59° C.), is essentially the same for all the vulcanizing periods common in industry. Certain of the synthetic mixtures show the same behaviour. With rubber compounds vulcanized with an accelerator and a large amount of sulphur, or sulphur alone, the brittle temperature was found to vary nearly linearly with the amount of chemically combined sulphur. All the usual rubber compounds have brittle temperatures above that of crude rubber. Any addition of asphalt or resin and of many oils tends to raise the brittle temperature a few degrees. Zinc oxide and carbon black, however, can be added in large quantities with small effect. The use of appreciable amounts of coarse fillers such as calcium carbonate, on the other hand, produces compounds with high brittle points after vulcanization. The various types of reclaimed rubber can be distinguished on the basis of their brittle temperatures, that from tyre tubes having the lowest.

Only two of the synthetic rubbers are comparable to natural rubber in elasticity at low temperatures. Synthetic rubbers also differ from natural rubber in having higher brittle temperatures than their compounds.

There seems to be little relationship between brittle temperature and the size of the molecule of the substance. In general, the large molecules have lower brittle temperatures than the small, but the change seems to be sudden rather than gradual. There appears to be a definite molecular size that must be attained before the brittle temperature characteristic of the material is reached. For rubber, this size corresponds to a molecular weight between 6,000 and 30,000, while for polyisobutylene it is between 1,500 and 10,000. The difference between the brittle temperatures for large and small molecules may be very great, as exemplified by polyethylene, which has a brittle temperature of + 5° F. (− 15° C.) for small molecules, and − 91° F. (− 68·5° C.) for the large.

FORTHCOMING EVENTS

Monday, June 8

ROYAL GEOGRAPHICAL SOCIETY (at Kensington Gore, London, S.W.7), at 5 p.m.—Major Offermann: "National Parks of the Belgian Congo".

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

WOMAN LECTURER IN GEOGRAPHY at the Brighton Municipal Training College—The Education Officer, 54 Old Steine, Brighton (June 10).

GRADUATE TEACHER OF MATHEMATICS AND ENGLISH in the Junior Technical School of the Castleford, Whitwood Mining and Technical College—The Director, Education Offices, Smawthorne Lane, Castleford, Yorks. (June 12).

FIRST TECHNICAL ASSISTANT (male) in the Economics Department—The Secretary, West of Scotland Agricultural College, 6 Blythswood Square, Glasgow (June 12).

LECTURER IN PHARMACEUTICAL SUBJECTS—The Principal, Leicester College of Technology and Commerce, The Newarke, Leicester (June 13).

LECTURER IN HORTICULTURE—The Registrar, The University, Leeds 2 (June 15).

HEADMASTER OF DERBY SCHOOL—The Acting Clerk to the Governors, Education Office, Becket Street, Derby (June 16).

GRADUATE TEACHER OF MATHEMATICS AND SCIENCE at the Grimsby Technical College—The Director of Education, Education Committee, Grimsby (June 17).

WORKS ENGINEER OF THE SALVAGE DEPARTMENT—The General Manager, Civic Centre, Birmingham 1 (endorsed 'Works Engineer') (June 20).

CHAIR OF NAVAL ARCHITECTURE, tenable at King's College, Newcastle-upon-Tyne—The Acting Registrar, University Office, 46 North Bailey, Durham (June 22).

PATHOLOGIST AND DIRECTOR OF THE CLINICAL RESEARCH LABORATORY—The Secretary and Treasurer, Victoria Infirmary of Glasgow, 40 St. Vincent Place, Glasgow, C.1 (June 27).

LECTURER IN CIVIL AND MECHANICAL ENGINEERING—The Secretary, Northampton Polytechnic, St. John Street, London, E.C.1 (June 30).

TWO ASSISTANT ENGINEERS with knowledge of River and Land Drainage Works—The Engineer, River Nene Catchment Board, Priestgate, Peterborough.

CIVIL ENGINEER in the service of the Government Railways, West Africa—The Secretary, Overseas Man-power Committee (Ref. 282/b), Ministry of Labour and National Service, Hanway House, Red Lion Square, London, W.C.1.

KNOWLEDGE AND ACTION

IT would be easy from the recent debates in the House of Commons on the war situation or those in the House of Lords on the organization for joint planning to derive a false impression of national dissension at a time of crisis. The temper of the House of Commons debate ran high at times, and very clearly there are intrigues and some resentment against the Prime Minister and his advisers, accentuated to some extent by the Government's apparent yielding to party pressure and sectional interests over the Beveridge report on coal rationing. In the House of Commons, indeed, the debate was at a lower level than in the House of Lords, concentrating rather on the demand for a real Chief of Staffs, as distinct from the Minister of Defence, than on the more fundamental need for a Great General Staff and for combined commands wherever the Services work together.

Such an interpretation, however, would mistake the whole tone of the criticism which the Government, like any Government in the third year of war when a militant and aggressive spirit is widespread in the nation, must always face from a free people. It springs from the call for proof of action: that the industrial resources are fully mobilized for the final stages of the struggle, and that the Government will finally assert its authority against private interests. It is primarily a call for leadership of the highest order, and springs from the growing recognition that the development of our maximum effort is a matter of science and knowledge and not merely tradition, and that it involves scientific management and wise administration as well as a commanding character and original intellect.

From many quarters has come evidence of the outstanding importance of administration and management at the present time. This is strikingly illustrated in the account of the Western Electric Company researches which is included in a recently published report "Fatigue of Workers: its Relation to Industrial Production" by the Committee on Work in Industry of the U.S. National Research Council. Social conditions as a rule are far more potent in their effect on efficiency than physical conditions. The most urgent task is that of solving these problems of command, production and industrial organization with foresight as well as with pertinence and expedition. We need the really great administrator of Bagehot who "thinks not only of the day but of the morrow; who is eager to extirpate every abuse and be on the watch for every improvement; is on a level with the highest political thought of his time and persuades his age to be ruled according to it in policy and in laws".

These words of Bagehot's describe almost exactly the mood of the nation and the essence of its criticism—lack of foresight, of resolution in dealing with abuses, and of earnestness in seeking for improvement. Given, however, administration in this large sense, concerned with the far-seeing regulation of future conduct as well as with the limited management of the present, it can only be fully effective with the full support and co-operation of management as of people. The soundest policy may be frustrated by inefficient or incompetent management, and no administration can remain unchallenged which fails to use its powers to remove whatever obstacles lack of vision, incompetence or private interest may place in its path.

If, therefore, it is a profound mistake to judge that the nation is not united and that the Government does not still command the support of an overwhelming majority of the people, it would be a fatal error not to recognize that continued support depends, not on what has been done in the past, but on what is done now to strike against the enemy abroad or against vested or sectional interests at home. The debates, like the coal situation itself, hold a warning of dangers which may rapidly develop in the absence of resolute leadership.

While the Beveridge scheme still holds the field on the consumption side as a scientific method of providing prompt, fair and effective rationing, on the production side the industry has to demonstrate its inherent capacity to solve its problems. For a quarter of a century it has set its face against all plans for reorganization advanced by independent investigators to secure efficiency. To this Sir Richard Redmayne's recent book "Men, Mines and Memories" is a significant witness. Rationing of fuel, in fact, without reorganization of the coal industry, would be a disaster alike from the point of view of our war effort and of the peace to follow, when an efficiently organized coal industry will be no less imperative.

There can be no question as to the growing scale upon which both scientific methods and knowledge are being made available. Prof. A. V. Hill's inspiring Gustave Canet Memorial Lecture to the Junior Institution of Engineers on May 22 on "Scientific Research and Development in the Empire" (see p. 653 of this issue) and the recent appointment of Dr. C. G. Darwin as scientific adviser to the Army Council, however, will not dispel the uneasiness which recent events have aroused in the minds of scientific workers and others as to the will of the Government to use scientific knowledge to re-shape the nation's economy when the needs of victory so demand. The Government has, it is true, accepted the main recommendations of the Citrine Committee, but the exceptions made may well prove crucial. The main recommendation of the report is that the principle of devolution must be applied to the office of the Minister of Production: "Just as the Minister of Production is charged with the duty of concerting and supervising the activities of the supply Ministries at the centre, so there should be in each region a representative of the Ministry whose duty it should be to concert and supervise the activities of the Regional Controllers of the Supply Departments."

The core of the Citrine Committee's plan is thus to have regional directors of production with this task of supervision to ensure the maximum degree of co-ordination. The Government, however, has already rejected this recommendation, and there are to be regional controllers, each of whom will indeed be chairman in his region of the regional board and of its executive committee, but he will at most be *primus inter pares*. It will still be impossible for regional facilities to be fully pooled and utilized. It is, of course, a distinct gain that most, if not all the most important, regional organizations for specific matters will now be centralized, physically as well as administratively, under the regional boards. The proposals making the regional boards cognizant of all the contracts placed and all the work in progress in their areas so that they can keep constant watch over the flow of orders and deliveries and over the use of capacity are to be welcomed, but it should be noted that vital exceptions have been made by the Government to the recommendation that the independent organizations established by the Supply Ministries for capacity-finding should be merged in the regional organization.

The regional organization of the Admiralty is to be excluded even when it is concerned with non-shipyard work. The regional organization of the Controller General of Machine Tools is to be excluded; and owing to the limitations imposed on Mr. Lyttelton himself in the matter of labour, the regional controller of production will have no more than joint powers with the regional controller of the Ministry of Labour over the allocation of labour. Given the right type of man of wide industrial experience and local knowledge visualized by the Committee, the new system may indeed prove better able to control effectively the local allocation of resources, to marry capacity and requirements, so that no capacity is unused and no requirements are unfulfilled. It puts a strain on the human factor, however, that the Citrine Committee's own recommendations might avoid, and it is difficult to escape the conclusion that once again the Government has missed a great opportunity presented by an admirable report of an expert committee.

There is, indeed, much to ponder in this penetrating analysis of organization. The first principles are sometimes laid down with disconcerting frankness. The emphatic and unanimous opinion that an efficient regional organization is an essential element in the effective prosecution of the War is accompanied by the equally emphatic opinion that an essential pre-requisite for the effective functioning of any regional machinery of co-ordination is a properly articulated system of devolution of executive authority. There is a tribute to the organization of the Ministry of Labour and National Service, and the Committee considers that the same method of organization could and should be equally applied to the other factors of production. Indeed, the report suggests that had there been developed correspondingly effective machinery for the collection of information about manufacturing capacity, for placing contracts and sub-contracts and for dealing with progressive problems comparable with that under central control for dealing with the man-power problem with which we entered the War, not only would the task of the employment exchanges in redistributing skilled labour for the purpose of building up new production units with unskilled labour have been made easier, but also, with adequate supplies of raw materials, the tempo of production would have been accelerated without a corresponding increase in the demand for machine tools or floor space.

There are trenchant observations on the failure to give the existing regional boards the opportunity of playing a continuous and effective part in securing the fullest possible use of the manufacturing resources of Great Britain, on the neglect to consult the Central Joint Advisory Committee, on the delays which result from failure adequately to plan the distribution of work and on the wastefulness of the establishment of capacity clearing centres of their own by the Supply Ministries. The Committee's ideas on the functions of the Boards, on their constitution, on the district organization and on those of the National Production Advisory Council which it proposes, are as clear and as sound as their views on decentralization, and their observations and recommendations are further supported by evidence in the Seventh and Eighth Reports of the Select Committee on National Expenditure, which have appeared since the Citrine Committee commenced its investigations.

The failure to implement the proposals of an impartial or expert inquiry is indeed one of the fundamental reasons for public anxiety at the present time, in spite of growing appreciation of the magnitude and efficiency of much of the national effort, as reflected, for example, in the recent report on conditions in a royal ordnance factory made by a deputation from a local trades and labour council which had received complaints as to idle hours, idle machines and lack of sympathy between management and workers at the factory. The deputation of six which visited the factory with the permission of the Ministry of Supply concluded its report with the words: "If this factory is a fair sample of those being run by the Ministry of Supply, their greatest critic will have to go very far before he can find a concern run by a private enterprise to equal them in the provisions made for the comfort and convenience of the employees." Management and administration have indeed great achievements to their credit, but the national effort will only reach its maximum when the standards of the best obtain everywhere and the latest advances in technique and knowledge are applied with wisdom, with firmness and with understanding both of men and materials. How much yet remains to be done in this field by the establishment of closer relations between management and worker is indicated by the Western Electric researches already mentioned.

It is at this same point that the debate in the House of Lords on May 5 betrayed misgivings. On the question of the organization for joint planning and the issue of a Great General Staff or a Chief of Staff as advocated by Sir Edward Grigg, little that was new was advanced, but there were significant observations as to the place of the scientific and technical experts. Lord Denman, for example, urged that fuller use should be made of the services of scientific men and technical experts, and suggested a chain of technical authority from the Army Council down to the military units in the field. He was concerned about the utilization to the best advantage of our great scientific and technical assets. Lord Swinton again emphasized the essential part which the integration of science and strategy and operations in the Air Ministry has played in making the victory of our pilots possible. In his view the Sub-Committee of the Committee of Imperial Defence, on which sat the Chiefs of Staff of the three Services or their deputies, the directors of development and production in Production Ministries or the Service production branch and the scientific advisers formed an integral part of the Combined General Staff, and gave the scientific side both the status and the opportunity of playing their part to the full; that common meeting-ground no longer exists, and Lord Swinton held that no organization exists by which scientific men can play their part in framing strategy to-day.

Mr. Lyttelton, it is true, has already indicated his plans for meeting this need in regard to the production side, but the marriage of scientific with operational staffs and in framing strategy as well as tactics is more than ever necessary to-day. Lord Milne pointed to the difficulties which arose when the whole of the supply technical services were taken out of the hands of the Army and transferred to the Ministry of Supply. That the Army should have been incidentally deprived in this way of technical advisers in such a technical war is, of course, a serious matter, and Lord Milne's plea for some return of staff and for a technical staff to consider research, preferably a joint technical staff linking the experience and requirements of the War Office with the activity and possibilities of the Ministry of Supply, is most reasonable. The need will no doubt be met, to some extent, from the new corps of Royal Electrical and Mechanical Engineers.

Lord Hankey himself, like Lord Trenchard, lent powerful support to the plea for a joint technical staff as part of the Combined General Staff and for bringing scientific workers into the central control of the War—a matter which need not wait on the appointment of the Chief of the Joint General Staff for which Lord Hankey pressed. Lord Chatfield's reply on this point was unconvincing, like that of Lord Simon. Organization of scientific research is already fairly effectively co-ordinated in ways which Lord Hankey as well as Lord Chatfield has outlined on previous occasions. That, however, is not the point at issue. The vital question is that of securing that the immediate study of strategy and tactics by the General Staff is conducted with an awareness of the possibilities which technical and scientific advance have put in our hands. That cannot be done by Service chiefs in isolation from scientific workers, or without some real appreciation of the scientific and technical factors involved.

The fundamental problem is the perennial one of relating effectively knowledge and action, whether against the enemy abroad or against any private interest at home which stands in the way of the nation's purpose. It calls for the application of those basic principles of the Haldane Report on the Machinery of Government which have too often been overlooked in debate as in policy: the integration of the field of work and the separation of planning from administration. In those principles lies the clue to the solution of the fuel problem as of that of production or the planning of combined operations. The nation has no reason to doubt that we possess the resources of materials, of technical or scientific skill, of men and women and of staying power and character required for victory, or even that leadership of the requisite calibre cannot be found for whatever onerous co-ordinating posts may be necessary. There is, however, real concern at the moment, less at the quality of our leadership than as to its determination to use both its authority and resources. The simplest demonstration that the Government accepts the principle that nothing shall be left undone that serves the national purpose would dispel such concern, but such a demonstration is imperative. No longer can the nation be left in doubt as to whether suaveness of manner is merely a cloak for tenderness to sectional interests when the national purpose demands swift, resolute and courageous action.

R. W. WOOD OF BALTIMORE

Doctor Wood, Modern Wizard of the Laboratory
The Story of an American Small Boy who became the most Daring and Original Experimental Physicist of our Day—but never Grew Up. By William Seabrook. Pp. xiv+335+13 plates. (New York: Harcourt, Brace and Co., Inc., 1941.) 3.75 dollars.

FEW American scientific men can be better known in Great Britain than the subject of this biography. The author has been in close touch with him, and has had every opportunity of gaining authentic information. The book is a popular one, and, as is perhaps natural and inevitable, has less to say about Wood's scientific achievements in developing resonance radiation and resonance spectra than about his personal adventures in various scientific and semi-scientific fields such as the aviation of early days, thawing frozen pipes, war work and scientific detection of crime. We are left with the impression that, successful as he has been as an experimenter, he could have done equally well as a conjuror or a variety entertainer.

The choice among many interesting topics for comment is almost embarrassing. Wood had for years been interested in filters transparent to ultra-violet light but opaque to the visual. The nearest approach to this generally available before his time was dense cobalt glass, which was used in Stokes's original investigations on fluorescence, but which is very far from the ideal. Wood introduced the use of nitroso-dimethyl aniline; but this, though it separates ultra-violet from blue much better than does cobalt glass, lets through a good deal of yellow. During the War of 1914–18 Wood gave his attention to the question again, and, arguing perhaps from the chemical analogy of cobalt and nickel, he tried a glass containing nickel oxide. This isolates the ultra-violet very satisfactorily, letting through no visual light, though of course it has the same limitation as ordinary glasses, that it stops wave-lengths shorter than λ 3000. This glass has many applications. One of them mentioned in the book is for the detection of secret writing by fluorescence. There is a very instructive incident told on p. 205. Wood was in Great Britain as a scientific-military officer and was being shown the secrets of the base censor's office. "What goes on in that cupboard?" he asked. It was too secret to be shown. "Ultra-violet light, I presume," said Wood. Eventually he was shown it. It was the old method used by Stokes in 1855, of cobalt glass to cut out the yellow and green from the source, and a yellow glass over the observer's eyes to cut out the blue. Wood happened to have a sample of his nickel glass in his pocket, and showed them how superior it was. Where could they get such glass? Answer: "Already in use at Portsmouth Dockyard; why have you not got them already?"

This kind of thing may well reduce scientific men who are called in to deal with war problems to despair. It was quite typical, and one would like to know whether in the interval of peace during 1918–39 anyone gave his mind to the question of how it was to be avoided in future. The answer would almost certainly be in the negative.

We are told how Wood took part in the investigations on the "spiritualistic" phenomena of Eusapia Palladino thirty years ago. He invented various ingenious methods of testing her, but does not seem to have had the opportunity to apply his methods satisfactorily. One of her phenomena was the bulging out of a curtain without obvious cause. Wood adheres definitely to the view that it was blown out by a current of air artificially produced. Readers of Sir J. J. Thomson's "Recollections" will find that he inclined to a quite different explanation. Eusapia was definitely caught in fraudulent manipulation by Dr. Hodgson and Mrs. Sidgwick, but it must be remembered that a paid medium has to 'deliver the goods' in order to earn a living; and if there really are genuine efforts, and if they will not come at pleasure, the temptation to imitate them fraudulently must be very strong. It is possible therefore to over-emphasize the unfavourable conclusions to be drawn from detected fraud. Some serious students of the subject still believe that genuine phenomena were, on occasion, produced by Eusapia, but, practically, their opinion can scarcely carry much weight.

This kind of investigation is difficult enough when we have only to attempt to gauge whether or not the paid professional mediums are deceiving the investigators. But if the investigators cannot be trusted not to deceive one another it indeed becomes almost hopeless. We are told of how Wood made use of some private knowledge which he happened to possess to deceive Dr. J. H. Hyslop and Sir Oliver Lodge. Hyslop had every reasonable ground for supposing that Wood could not have possessed this knowledge normally, but he happened to be wrong in so thinking, and Wood, pretending to be in a kind of dream state, intentionally led him to believe that it had been acquired in some supernormal way by telepathy. If this had been immediately afterwards confessed, and used to point a moral of the necessity for caution, it might pass. As it was not confessed, we do not think that it was justifiable to treat a brother scientist and a sincere searcher after truth in this way. Practical joking of this kind is a dangerous game, and may inflict grievous injury on the victim. For example, Paul Kammerer is said to have been driven to suicide because thoughtless students had deceived him by faked evidence for the inheritance of acquired characters. In any case, the incident reads oddly in a chapter entitled

"Debunker of Frauds". The boot seems rather to be on the other leg. The most favourable view is that Wood was on this occasion, as the title-page indicates, acting like a boy who has never grown up.

It is understood that Wood's energies have, of recent years, been largely devoted to the problem of ruling diffraction gratings which will throw most of the light into a single spectrum. In stellar spectroscopy there is no more important experimental problem than this one, and probably none better suited to our hero's peculiar talents. The need is always for more light, and the enormous sums spent on large telescopes are eloquent of this. But for many purposes it would be as good or better to double the amount of light thrown into a given spectrum as to double the area of the telescope objective; and, once we know how to do it, the cost would be incomparably less. So far, little is known in Great Britain of the details of Wood's methods, except that he makes his rulings on aluminized glass. We see in the bibliography of this book that a paper was due to appear in the *Astrophysical Journal* for December, 1941, but in fact no number appeared at all for that month. There are, if we understand rightly, hints of very large transmission gratings also.

We recommend the book as amusing reading, and are glad that a vivid personality has been recorded as a contribution to the history of science in our era.

RAYLEIGH.

EDUCATION AND NATURE

Truth and Fallacy in Educational Theory

By Charles D. Hardie. Pp. x+151. (Cambridge: At the University Press, 1942.) 6*s*. net.

MR. C. D. HARDIE's book is the kind of book which causes one to look backward, to look around, and then to look forward. He writes as a philosopher, and therefore as one engaged in an obstinate effort to think clearly. Though he does not express it in so many words, his real aim seems to be to show up the confusions in educational theory that have arisen from ambiguities in the use of the term 'Nature'.

As far back as the 1860's Herbert Spencer wrote his forceful and influential essays on education "according to Nature". He was consciously indebted to Pestalozzi, who in turn drew his inspiration from Rousseau. Speaking generally, we may say that writers of this type held that intellectual education should be based upon sense-impression, since that is the method of Nature, and that moral education should be based upon the discipline of consequences, that again being the method of Nature. Spencer waxes almost lyrical in praise of the blind forces of Nature, as against the meddlesome activities of parents, nurses and teachers. But during the closing decade of the century, there came to Great Britain from Germany, chiefly by way of America, the opposing influence of Herbart, who had no use for a theory of education which belittled instruction and guidance. For a child running down a steep declivity the intervention of the mother was just as much a part of Nature's plan as the pitiless operation of the law of gravity. Herbart's whole system exalted the province of parent and teacher, so much so indeed as to incur with justice the charge of over-direction. Hence the welcome accorded to the movement associated with the name of John Dewey. According to him, the way appointed by Nature, if we only understood her, was that of letting the child take the lead, not the teacher. This principle, embodied in the so-called project method, has in some hands been carried so far as to sacrifice what is best in the traditional 'grind', and to provoke a protest from Dewey himself. That is where our 'progressive' teachers now stand.

In his first three chapters Mr. Hardie passes in critical review each of the movements above described. Much of his criticism has, of course, been anticipated by previous writers, but the modern ring in his remarks is refreshing, as when he shows that the laws of arithmetic have nothing to do with little operations with beads and beans, that it is far from being 'unscientific' to accept results on authority, and that Herbart's conception of many-sided interest—for which Mr. Maxwell Garnett would substitute a single wide interest—has much to say for itself if understood in a deeper sense than that of merely "making things interesting".

Proceeding from these discussions of ambiguities and fallacies, the author in his fourth chapter sets down what he conceives to be the basis on which an educational theory should be built. Recalling many definitions of education, showing some agreement and some important differences, he asks whether there is one that is right and all the rest wrong. In the course of the chapter there are valuable discussions of the elusive conception of instinct, of the still more elusive conception of intelligence, of the transfer of training, of heredity and its importance (or otherwise) for education, and lastly of the conception of value. This final topic leads the author back to his question whether there is one definition of education that is right and all the rest wrong. He ends with a plea for tolerance, for no one of them is right and no one wrong.

The reviewer feels moved to add that the book makes unnecessarily difficult reading, partly because of the inherent obscurities of the subject, and partly through causes that seem to him remediable.

T. RAYMONT.

FAULTING AND DYKE FORMATION

The Dynamics of Faulting and Dyke Formation: with Applications to Britain

By Dr. E. M. Anderson. Pp. xii+191. (Edinburgh and London: Oliver and Boyd, 1942.) 15*s*. net.

THIS book can be warmly recommended to geologists, who will read it with great interest and profit. The theory of principal stresses had long been applied by engineers to explain fractures in materials, but it was the author who first applied it in explanation of the main types of rock fractures or faults well known to geologists. From field experience these had been classified into three main types called strike faults, dip faults and oblique faults which conformed to neither of these directions. With increasing knowledge it was found that the majority of those in the first class were overthrusts while those of the second class were mainly normal faults. It was only later that the oblique faults were better understood; many of these have now been proved to be associated with some horizontal movement parallel to the earth's surface, and they have been called tear faults, transcurrent faults (the name favoured by the author), and a variety of other names.

In 1905 Anderson, by applying the theory of principal stresses, in conjunction with Navier's principle of internal resistance to shearing proportional to the normal stress, succeeded in elucidating the general stress conditions that might give rise to these three types of fractures and showed that faults in general conformed to the deductions from the theory. Since then he has applied the same principles in explanation of intrusions of cone-sheets or inclined sheets characteristic of the Tertiary Igneous province of the Inner Hebrides. In the book under notice the latter are excluded, but dykes and sills are brought within the same principles and some interesting deductions are made regarding their possible mutual relations, which are discussed in some detail.

It is considered that fault fractures are in general produced by shearing stresses, whereas in the emplacement of dykes the fractures are the result of tension or at least of pressures across the trend of the dyke substantially less than the pressure of the magma at the point of rupture.

The principal stress theory as applied to faulting is now fairly well known among geologists, and some years ago the Geological Society of London organized a joint meeting with the Royal Astronomical Society (Geophysical Discussion) at which its relation to the formation of faults and other fractures was discussed. Its re-statement and the special applications dealt with in this book will, however, be genuinely welcomed.

Several areas in Great Britain are described, and the general stress conditions which are revealed by their fault systems are deduced. Attention is directed to those regions where the faulting is either of Caledonian or Armorian age but mainly the latter, since faulting of that age has been more closely studied on account of its effects in coal mining. The investigation is therefore only a beginning, but it is likely that its presentation in a form which can be easily understood will result in a closer study by geologists of the stress conditions that prevailed in other areas and of other periods, and thus help to build up the tectonic history of the British Isles and other regions throughout the ages.

In the presentation of the theory in 1905 the effects of superposing shear stresses on the principal stresses were suggested. Its omission in this book leads the author into difficulties in interpreting certain faults in South Wales and elsewhere. D. W. Phillips has shown the importance of taking these into account in explaining induced cleavage produced near a working coal face.

The author perpetuates the mathematical fiction of tension in the earth's crust, which is difficult to appreciate in view of the fact that fault fractures must, in general, have their origin at a depth where high pressures must prevail in every direction. Tension is apparently regarded in the same way as a relief of pressure. It is difficult to conceive of a stress deep in the earth's crust changing in a short interval of time from a pressure to a tension in the same direction but mathematically a relief of pressure is perhaps regarded as a tension superposed on the pre-existing pressure

In general, if one horizontal stress at some depth is increased, an element of the crust is shortened in the direction in which it is applied and lengthened in all directions at right angles, the amount of extension being given by Poisson's ratio. The extension is, however, opposed by the resistance of adjoining elements, and in this sense an increase of pressure in one horizontal direction brings into play a pressure in directions at right angles which is in a certain ratio to the increase of applied pressure.

The author considers increase and relief of pressure by reference to an imaginary 'standard state' where the horizontal pressures are approximately equal to the vertical load of the column of rock. This conception tends unduly to divorce the phase of faulting from preceding phases (such as folding) during which the conditions have long been different from the standard state.

It would take too long to follow the author in his detailed analysis of various areas of faulting. A study of the post-Carboniferous faulting leads to the conclusion that the directions of stress during the formation of these faults remained remarkably similar over a large part of Great Britain. In particular examples, however, sufficient allowance is not made for local variations in the stresses which controlled the directions of certain faults. One example occurs in the South Wales coalfields and South Pembrokeshire. In the latter area strike faults and tear faults occur in association with one another and with folding. In the main coalfield there is also some folding, but the dominant structures are the 'north-north-west' faults. The author is inclined to group these with the north-north-west tear faults of South Pembrokeshire with which, however, they have little in common. The fold axes of the coalfield change gradually in direction from east-north-east in the east to about east-west in the west, and taking these as an indication of the direction of the greatest horizontal stress, the faults lie very near that direction and thus conform to the stress conditions of normal faults, which in fact they are.

In the same field there are complex belts called 'disturbances', of which one near the Tawe Valley is but an example of many parallel structures; these are generally believed to be younger than the north-north-west faults. They are, however, probably a reflexion in the Palæozoic rocks of deep-seated fractures in the pre-Cambrian floor which are liable to move with any great increase of stress in the area. Two faults are deflected in crossing the Tawe disturbance, as shown in Fig. 21. If, however, a counter-clockwise shear in the direction of this disturbance is superimposed on the principal stresses of the adjoining region, the deflection of the two faults is explained.

Another great fault belonging to the same general system is the Church Stretton fault, which is now under investigation for a great part of its length. This fault belt is a symptom of deep-seated conditions which may have caused local modifications in the general stress distribution that prevailed outside the belt at various times.

There is an interesting discussion of the conditions necessary for the production of dykes and sills and for the passage occasionally observed of one into the other.

The reader is cautioned against accepting the statement of enormous horizontal displacement along the line of the Great Glen fault until more critical evidence is produced than has hitherto been made known.

O. T. JONES.

SCIENTIFIC RESEARCH AND DEVELOPMENT IN THE EMPIRE*

By PROF. A. V. HILL, O.B.E., F.R.S., M.P.

Canet

IT might seem a bitter irony of fate that a lecture should be given in memory of a great French engineer, in the field of artillery, who lived so long in England and had so many intimate connexions here, at a time when a Government of traitors in France is actively aiding the common enemy against her ally. Were Jean Baptiste Gustave Adolphe Canet alive to-day, we know very well where his heart would be. "It would be impossible", it has been said of Canet, "to record his innumerable acts of consideration and regard for the Junior Institution of Engineers", of which he was an honorary member, a vice-president, and president in the year he died. It would be impossible for an Englishman who has been intimate with Frenchmen of his kind not to believe that France will rise again, purged by her misfortunes, to better things. The world cannot do without a nation which can produce men of his genius, whether for engineering, philanthropy or friendship.

Empire Science

France, however, does not come very far into the story of scientific research and development in the Empire, which I have to tell to-day, though it is true that the Dominion of Canada was originally French, that a significant part of its culture is still French, that scientific men and engineers of French origin take an important part in Canada's life, and that Henri Laugier, head until the fall of France of the French equivalent of the Department of Scientific and Industrial Research, is busily engaged there now in work devoted to our common cause. Predominant as may be, so far, the Anglo-Saxon part in Empire science, significant contributions have been and are being made by almost every national group within it. It is a common enterprise of all the peoples of the Empire, biased locally in direction by local requirements and facilities, but carried on everywhere in the same spirit, by the same methods and with the same standards of accuracy and objectivity.

The chief object of this lecture will be to try to indicate how closer and more effective scientific co-operation within the Empire can be obtained.

Imperial Collaboration in War Research

In the early days of the War my colleague and co-secretary of the Royal Society, Prof. A. C. Egerton, and I, convinced of the enormous prospective advantage to our common war effort of close consultation with organized science in the Dominions, discussed the matter with Sir William Bragg, then president of the Royal Society, who, from his twenty-two years at Adelaide, was very well acquainted with science in Australia, and had close connexions with scientific men in the other countries of the Empire.

Fortunately, Dr. R. W. Boyle, of the National Research Council of Canada, was in London at the time—having escaped from Poland, where he had been on holiday when war broke out—and discussions with him then helped to bring our plans to later fruition. That winter also, Dr. Madsen came to England from Australia to obtain information about certain important scientific and technical developments here which must be of vital importance now, with Australia in the front line of battle. Then early in 1940 the opportunity occurred of going for a period, on behalf of the Air Ministry, to the British Embassy in Washington; an opportunity which I seized, seeing in it the means of making arrangements for scientific collaboration, on the one part between Britain and the United States (not yet in the War, but warmly sympathetic), on the other part between Canada and the "old country", as they affectionately say. There was no difficulty of any kind in Canada —only anxiety to see the thing put through—and plans were accordingly made. In Washington one was confidently assured that the President would instantly respond to an approach from the British Government—which, in fact, he did when the approach was ultimately made.

In August 1940, the Canadian plan was started off by Prof. R. H. Fowler going to Ottawa to act as scientific liaison officer with the National Research Council, and to develop an informal connexion with scientific men in the United States. A little earlier the National Defense Research Committee had been formed in Washington, with Dr. V. Bush as chairman. Finally, in the autumn of 1940, Sir Henry Tizard took a mission to Canada and the United States. No words can overstress the importance of what was achieved by that mission and by Fowler's strenuous efforts.

In the meantime another plan we had had at the Royal Society, since the summer of 1938, also reached shape and fruition, and the Scientific Advisory Committee of the War Cabinet was formed—most fortunately under the chairmanship of Lord Hankey.

It is difficult now to remember good-humouredly the further unnecessary difficulties which arose, but finally an office of the National Defense Research Committee was established at the American Embassy in London and a British Central Scientific Office in Washington; while representatives of Canadian and Australian science were appointed to the offices of their High Commissioners in London. To these a continual flow of scientific men and engineers, engaged in various projects, has come; while in the persons of Mr. Nevill Wright, of the New Zealand office, and of Colonel B. F. J. Schonland, of South Africa, representatives of those Dominions also have been available in our counsels. Attempts have been made, but unsuccessfully so far, to establish similar arrangements with Indian science.

Speed in Travel and Transmission

The contributions which have been made already by this organized collaboration have been very important, and now that it is running sweetly greater results still will accrue. It is quite impossible to achieve more than a small fraction of what is needed merely by correspondence and by the circulation of reports, drawings and specifications: personal contact and personal initiative are needed also, for which it is necessary to provide, on the one hand permanent or semi-permanent scientific liaison officers in the various centres—as has now been done—on the other, means of rapid transport for short visits by experts either way. The rapid transfer also of correspondence, documents and drawings, and of small samples, is essential—for the former, given air transport, the microfilm method, which is rapidly coming into its own, is of very special advantage.

---

* Substance of the ninth quadrennial Gustave Canet Memorial Lecture of the Junior Institution of Engineers on May 22.

Great difficulty is still experienced from slowness of travel and transmission of scientific people and information. At present official communication with the United States may take anything from two to six weeks. It is too slow. With Australia and New Zealand and South Africa now it is essential that safe and rapid transfer of information should be possible.

The Future

The presence in London of so many representatives of science in the Empire, in close and frequent contact with their colleagues at home by visits and correspondence, offered the opportunity of instituting a discussion of joint problems, quite apart from those immediately connected with the War. The persons concerned would naturally be very busy with urgent work, but the question of future scientific collaboration within the Empire, and, arising from that, with the United States, was so important that a general consideration of it at occasional informal meetings would be possible and fruitful. The two main objects of discussion might be, first, emergency problems of the immediate post-war era, and, secondly, the possibility of making the most of our common scientific resources and heritage for improving both scientific knowledge itself and the life of the peoples of the Empire.

With this in view, the officers of the Royal Society called a conference in October 1941 of the representatives of the countries of the Empire, together with the officers of the Society, the secretaries of the Agricultural Research Council, the Medical Research Council, and the Department of Scientific and Industrial Research, and others. The president, Sir Henry Dale, in opening the conference, mentioned the ideal of continued collaboration in time of peace, saying that the material structure of society depends on science, and that if reconstruction was to be tackled on a properly international scale science must once more become an international activity. A first step towards this could probably best be taken on the initiative of scientific men of the British Empire and the United States together; for example, the International Scientific Unions would have to be started again, if possible on better lines. Sir John Madsen, from Australia, felt sure that great interest would be taken by the other Governments of the Empire in the view of the United Kingdom Government in this matter; he suggested that an extension of facilities for meeting and working with their colleagues elsewhere would greatly improve collaboration, and that the first activity of a committee to be set up, following the conference, might be to explore the facilities at present available and the means of extending them. General A. McNaughton, as president of the National Research Council of Canada, offered every possible help and support for the objects of the conference, and considered that the interchange referred to should occur, not only between universities, but also between industrial and Government laboratories in the different countries, including if possible the United States: he did not believe that if scientific people were convinced that this interchange was necessary, financial difficulties need stand in the way. Sir Edward Appleton, secretary of the Department of Scientific and Industrial Research, hoped that permanent liaison officers would be maintained in scientific and technical matters in peace-time as well as war. Sir Henry Tizard foresaw financial stringency as regards interchange for educational purposes, as distinguished from specific research, but urged that exchange would be particularly valuable between the universities of the Empire during undergraduate years, especially in applied science.

Lord Hankey welcomed the calling of the conference and said he felt sure that during the exploratory work proposed to be undertaken the inquiry would branch out and important new points of interest emerge. He referred to the advantage of having a scientific advisory committee with a Cabinet Minister as chairman, to bring science into direct contact with the centre of government. If in each country of the Empire the scientific organization was thus arranged, there would grow up gradually an official appreciation of science, since from time to time, as ministries changed, one Cabinet Minister after another would be taking a special interest in science. Colonel Schonland (South Africa) urged the importance of considering the scientific needs and possibilities of Africa as a unit; and he added in a later letter to me: "It is not a question of money at all, but of brains and sound organization."

A number of others took part in the discussion, and it was recognized that later on it would be most desirable if possible to secure close collaboration with official and unofficial science in the United States; all were agreed that popular lecture tours did not at all fulfil the purpose in mind; special reference was made to co-operative work in agriculture; and the conference then appointed a committee to look into the various proposals made.

I have described the discussion at this conference in some detail because of the great importance of several of the points raised, because it may be the beginning of an important movement towards closer scientific collaboration, and because many in other parts of the world may be glad to know of what is going on. It is not easy in times like these to get much more work out of busy people, but the committee appointed (which, in addition to representatives of the Royal Society and of the Dominions and India, has included Sir David Chadwick, secretary of the Imperial Agricultural Bureaux) has met already seven times; and owing to the initiative of its secretary, Dr. Alexander King, scientific liaison officer in the Ministry of Supply, much information has been collected and discussed on science in the Empire and on facilities for interchange in advanced study and research. The representatives of a variety of interests have been interviewed, including the research associations, the Universities Bureau of the British Empire, the 1851 Exhibition Studentships, the Leverhulme Fellowships and the British Council; and a variety of suggestions have been made and followed up. All this will serve as the basis for further exploration and planning, and it is intended next to proceed to the discussion of concrete proposals to improve the machinery of collaboration.

The Colonies

In all this discussion there has been no specific reference so far to the Colonies, only to the Dominions and India. The scientific problems and the possibilities of scientific development in the Colonies, Protectorates and Mandated Territories are, however, of great importance, and considerable attention has, in fact, been devoted to them for some time. In 1927, for example, the Colonial Office formed a Colonial

Medical Research Committee, a mixed body of administrators and scientific members. Little, however, was done, but in 1936 the Colonial Office asked the Medical Research Council to supervise research in tropical disease, a project which this time seemed likely to be highly successful, but was interrupted by the War. Under the Colonial Development and Welfare Act, 1940, two funds have now been created, one of £5,000,000 a year for ten years for Colonial development and welfare generally, one of £500,000 a year without time limit for Colonial research. A director of a proposed Colonial Products Research Institute, it is hoped, will shortly be appointed; the products in question are those of biological origin. A Colonial Research Advisory Committee is to be set up under the chairmanship of Lord Hailey, which will not only advise on the expenditure of £500,000 per annum, but also will "advise upon and co-ordinate the whole range of research in Colonial studies".

The Imperial Agricultural Bureaux, founded in 1929, are concerned with agricultural matters in the Colonies as well as in all the other countries of the Empire. The Imperial Institute, founded in 1887, has five main departments, dealing with the commercial, industrial and educational interests of the Empire, particularly in relation to raw materials, to research upon them and to the development of their use and supply; minerals, plant and animal products, exhibition galleries, intelligence, statistics, library and laboratories are among its many activities. The Institute has many difficulties to contend with, not least the fact that with its enormous field of interest its annual budget is only £48,000, less than 1*d.* per square mile of the Empire whose natural resources it surveys, less than 3*d.* per square mile if calculated for the area of the Colonies alone!

An Africa Research Council

One of the suggestions made to the British Commonwealth Science Committee, to which I have referred, is that for the purposes of scientific research and development Africa might be treated as a separate unit, the work being a joint concern of the scientific organizations of the United Kingdom on the one hand and of the Union of South Africa on the other. Among the subjects to be treated, for which Africa as a whole has special needs and opportunities, might be tropical diseases, social anthropology and race relations, native languages, ethnology, geology, geophysics and meteorology.

The formation of an Africa Research Council, a joint interest both of governments and private benefactors and individuals, as so many of the best of our British institutions are, might lead to developments of the kind required for specifically African problems. There is no other region in the world in which the same variety of researches is needed, all to some degree for geographical and political reasons inter-related; if the different elements of this variety could be treated each as part of the whole scientific problem of Africa, and made to fit into the other elements, the results might be much more satisfactory and more far-reaching in importance than if all were studied separately according to subject and locality. A good example of the need for such an Africa Research Council is shown by the failure, before the War, to get a badly needed geodetic survey of Africa started, because there was no body in existence to father it.

It is clear that a scheme of this kind must wait for better times: it would involve the setting up of a central office and council, the collection and allocation of funds, the distribution of work and interests between it and other agencies, and the foundation of new or the development of existing research institutes, in Great Britain or in various parts of Africa. In view, however, of the obvious advantages it might have, it may be well to throw it now into the arena of discussion, so that on one hand it may be thought about, on the other so that no action may be taken in the meantime which might make it in the future more difficult to realize.

Existing Scientific Agencies in the Dominions and India

The scientific organization of the Dominions and of India is so highly developed, in universities and research institutions, in industry and under Government auspices, that no account of it, valuable as one would be, could be given in a lecture. The National Research Council of Canada is the equivalent, roughly, of the Department of Scientific and Industrial Research and the Medical Research Council in Great Britain, and of the research departments in the Service and Supply Ministries. It has great resources and a magnificent record, particularly in the present War. In Australia, the Council for Scientific and Industrial Research is the approximate equivalent of our Department of Scientific and Industrial Research and under the able leadership of Sir David Rivett it has made very important contributions both in peace-time and for the defence of Australia in the last three years. In South Africa the National Research Council, with advisory functions, and the National Research Board, with administrative functions, together with the South African Institute for Medical Research, take a prominent part in scientific developments in the Union. In New Zealand the Scientific and Industrial Research Department plays an analogous role. In India, the Board of Scientific and Industrial Research, under the able directorship of Sir Shanti Swarupa Bhatnagar, has taken a very active part in mobilizing the scientific and technical resources of India since its foundation in 1940; the Survey of India, the Zoological Survey, the Botanical Survey and the Geological Survey, the Indian Science Congress and the Indian Research Fund Association (medical) all have obvious and important tasks to fulfil.

This is merely a selection for purposes of illustration; Government agencies, universities, and private benefactions are responsible for innumerable others: in education and research; in application to defence, to industry and transport and to medicine and public health; in agriculture; for improving knowledge on one hand and the life of the people on the other. In each of these countries science and the scientific outlook, research and its application, make up a great and living organism. No doubt in each of them much remains to be done, as it does in Great Britain; but what is chiefly needed, and what will help beyond any other single factor in forwarding the promotion of science itself and its application to the public welfare is closer contact, more intimate knowledge, quicker and more frequent communication, a better intelligence and information service, easier exchange, between the several living parts of the whole living organism of science spread across the Empire, and—I should like to add—the United States.

Freedom of Research

I have talked a good deal about co-operation and collaboration, but not—you may have noticed—about co-ordination. Science is a free growth, and, as Sir David Chadwick recently wrote in a note to the British Commonwealth Science Committee: "much of the most valuable research must be free . . . To many who rightly prize that characteristic of research, the word 'co-ordination' denotes 'sinning against the Holy Ghost'. . . . One must bear in mind that the countries in the British Commonwealth have developed on different lines. These lines may meet in the end, but their starting points have been poles asunder."

This warning must be remembered. Co-ordination is necessary, within limits, to help to guide research into profitable channels and lest waste, overlap or its converse may occur ; but in dealing with a group of proud and independent nations, however friendly and co-operative, we and they must all beware of attempting to introduce a degree of direction, authority or control which many will certainly resent. The Imperial Agricultural Bureaux represent an ideal of equal partnership in the co-operative dissemination of information on research. There is no reason why similar collaboration should not be built up about similar bureaux in other scientific subjects, or, for example, around the libraries and information services of the industrial research associations, the Imperial Institute, or other similar bodies in Britain or the Dominions. London need not necessarily be the focus for all. Co-ordination will then come naturally with increase of knowledge, contact and information. Co-operative research is a living, growing organism ; it must be carefully tended, not just pushed into a mechanical framework planned from outside.

We hear a good deal about planning, and planning of scientific research we must certainly have. An Africa Research Council, for example, if it were to be set up, would require a deal of planning. Freedom, on the other hand, is the material and moral basis of the British Commonwealth, and requires explicit recognition in all we do or say. In some way planning and freedom must be combined. There is in this, as in most human affairs, an optimum mixture, the right proportions of which we must seek and find. This optimum must be aimed at, here in Britain, in the action and reaction of free science and free initiative with science and initiative provided by the State. It must be aimed at independently, perhaps with a different final mixture appropriate to their conditions, in each of the countries of the Empire ; and it must be sought in the freely accepted co-ordination of the scientific activities of the different parts of the whole Commonwealth.

My own faith is that improvement in knowledge, contact, communication, familiarity between the scientific people of the Empire—and of the United States—will allow that co-ordination quietly to be achieved, the planning to be successfully undertaken, without any violation of the freedom on which we all set so great store, about which we are all so sensitive. It comes back again, therefore, to quickness, ease and facility of travel, transport and communication—things which engineers, in one way or another, must provide. For I believe that scientific people—and engineers—are on the whole rather more reasonable and practical—if not very much—than other folk, and that when we get to know each other by working together on a common job, we are generally ready to appreciate and understand the other fellow's difficulties and virtues and his point of view. The common job exists obviously enough in the scientific development of the Empire, for the improvement, as I repeat, of knowledge and of the life of its people : the important thing therefore is to improve the methods and technique of getting down to it together.

FAMILY ALLOWANCES

By D. CARADOG JONES

University of Liverpool

THE subject of family allowances—assistance given in cash rather than in kind, to meet the cost of maintaining children during the period of their dependency—bids fair to become a live political issue. It is now nearly twenty years since Miss Eleanor Rathbone's much-debated book, "The Disinherited Family", was published, wherein she made a powerful and piquant plea for the introduction into Great Britain of some system of communal payment for the important task of rearing children. Other countries had seized the opportunity presented by the War of 1914–18 to slip in the thin edge of the wedge and the breach thus made was afterwards widened, but Great Britain allowed that chance to pass.

It may seem odd that a time of war should be considered appropriate even for the discussion of such a subject. There are several reasons to account for it. When things are upside down, people are more ready to listen to revolutionary proposals. By grafting on to the normal bargaining process for settling wages a scheme of children's allowances, the needs of the family are taken into account as well as the skill and merit of the worker. To accomplish this would clearly be difficult unless prices are rising, and they invariably do rise during wars ; and if wages are to keep step with the cost of living, there is much to be said for a sliding scale graduated according to the number of mouths to be fed. The payment of war-time separation allowances encourages, too, a widespread habit of expecting the weekly income to conform to the size of family. Moreover, under war conditions, the unmarried young man, if left to earn good money by making munitions instead of being obliged to serve in the Forces, would be unlikely to wish to attract critical attention by complaining if his pay does not rise in the same proportion as that of the man with a family.

Trades union leaders in Great Britain have in the past been either antagonistic or only lukewarm in their attitude towards family allowances, largely from a fear that they might be used to depress their standard of living. In countries such as France and Belgium there was the same fear, but it did not persist in any marked degree after the introduction of a compulsory State system covering a large proportion of the employed population. Under the type of scheme favoured by these countries, the allowances were financed by equalization funds, to which contributions were made by all the employers engaged in a specified industry or resident in a defined region. The sum put into the pool by each employer was proportional to the number of his workers or to his total wages bill. This simple device overcame the difficulty that some firms might otherwise have been tempted to employ only single men or men with very small families.

Advantages Claimed

Although the British Government may be presumed still to maintain an open mind as to the wisdom of introducing family allowances, a step forward has now been taken by the issue of an official memorandum on the subject (Parliamentary Paper, Cmd. 6354. London: H.M. Stationery Office. 2*d.* net) following a deputation of members of Parliament which the Chancellor of the Exchequer received in June of last year.

Advocates urge the disadvantage under present conditions, when everything possible should be done to avoid inflation, of meeting the rise in the cost of living by a flat increase in wages which puts extra money into the pockets of many people who do not need it. Any additional sum that can be spared towards wages, if distributed in the form of family allowances, would go, they say, some way to prevent malnutrition in households containing several small children. There is also the familiar claim that family allowances may arrest the decline in effective fertility. On this point the evidence derived from the experience of France and Belgium is not very conclusive, according to D. V. Glass, who has made a careful examination of the material. In his "Population Policies and Movements", published early in 1940, he says (p. 202): "it is evident that they have not been influential enough to cause a rise in fertility, or even to stabilise fertility at its already low level of five or ten years ago. On the other hand, it is probably true that the family allowance system in France has helped to reduce infant mortality, and it is likely that this has also been the case in Belgium."

When families are not far from the border-line of poverty, there is no doubt that the advent of babies aggravates their economic condition, which inevitably reacts on the health and nutrition of all the members of the household. Evidence of the appreciably higher incidence of poverty among children than in the general population was obtained in the course of three social surveys, namely London, Merseyside and York. It is evident, therefore, that to subsidize the maintenance of children should be one profitable way of attacking the problem of poverty. But, while agreeing to this, it is still possible to hold the view that it might be wiser to give the subsidy in kind—better provision of infant welfare services, school dinners, improved housing, or some other form of social assistance—rather than in the form of a cash allowance to the parents, who might be tempted not to spend it on the children.

Contributory and Non-Contributory

The main arguments for and against family allowances are summarized in the Government White Paper without discussion. The cost is then estimated on various alternative assumptions. Thus, an allowance might be paid in respect of every child in the family; it might be paid only in respect of the second and subsequent children; or it might be paid only in respect of the third and subsequent children. Again, the scheme might apply to all parents, or it might be limited to parents below an agreed level of income, or to parents who are already subject to compulsory national insurance. The advantages and disadvantages of these various alternatives are briefly examined in the memorandum. Other equally important questions arise for consideration. Should the scheme be paid for by the State, the employers, the parents of the beneficiaries, or by some combination of these three parties on the principle adopted for national insurance purposes? Finally, if the scheme is to be contributory, should it be also compulsory?

Let us start with a contributory scheme. It is estimated that, in order to provide a flat-rate allowance of 5*s.* a week for each child of parents in insurable employment, the child to be less than fifteen years of age unless still receiving full-time education, the weekly contribution which would be required of every employed person (other than juveniles presumably) would amount to 2*s.* 8*d.* a week. As a matter of practical administration, the scheme would in this case no doubt be fitted on to the existing contributory pensions scheme, and the contribution conditions would be the same for both; in other words, the State, the employer, and the worker would each contribute a share of the total estimated cost. It is further assumed that full contributions would be paid into the pool in respect of members of the armed forces, that equal contributions would be paid in respect of men and women, and that parents would continue these payments even when in receipt of benefit. The last-mentioned assumption means in effect that the nominal weekly allowance of 5*s.* for the parent with one child would be reduced to 2*s.* 4*d.*

No allowance has been made in this estimate for the cost of administration and, in view of the relatively small net benefit available, it would seem that a non-contributory scheme—though more costly to the public in general—might give a better return for the labour and expense incurred. We pass on therefore to consider a scheme where the whole expense would be borne by the Exchequer.

The estimated gross cost of a non-contributory scheme giving allowances at 5*s.* a week in respect of each child as before is £132 million a year. If the first eligible child in each family were excluded from benefit, the gross estimated cost would fall to £58 million a year. These calculations are made on the assumption that the allowances would be available for all classes of the population irrespective of their incomes. Additional estimates have been made, however, on two different assumptions: (*a*) that the benefits would only be available to parents with incomes of £260 a year or less; and (*b*) that the benefits would only be available to parents already compulsorily insured for contributory pensions or, if not so insured, whose incomes amount to not more than £420 a year.

Clearly, the administration of the first of these two alternative schemes would involve a means test and for that reason it might not be very popular. The second scheme would be much easier to administer, because the bulk of the families eligible for benefit are already dealt with for national insurance purposes. Confining our attention accordingly to the (*b*) scheme, it is estimated that the gross cost of providing 5s. a week for every eligible child in the family would be £124 million a year. If the first eligible child were excluded from benefit, the gross annual cost would be reduced to £55 million.

These are the gross estimates, but the actual net cost under each head would be rather less, because there would be some saving of expenditure on children's benefits provided by existing social services of one kind or another. These benefits would naturally be revised to avoid duplication with family allowances. For example, where the needs of the family are assessed for the determination of benefits, as in making grants of unemployment assistance, family allowances would have to be taken into account.

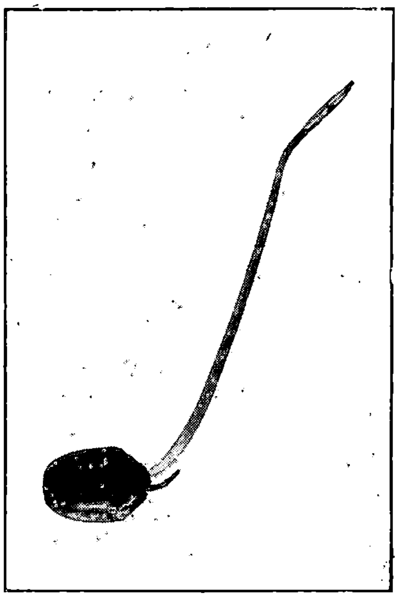
It is impossible to estimate all such savings with precision. In so far as an estimate can be made, the total sum saved is put at £7 million a year for a scheme covering all eligible children, and at £3 million for a scheme covering all eligible children except the first in each family. These same figures are used whether the benefits are to be available for all parents or confined to a particular class. It follows that for a universal scheme, covering all parents, the estimated net cost under existing conditions to provide a flat-rate allowance of 5*s.* for every child less than fifteen years old, or over that age if still receiving full-time education, would be £125 million a year; and to provide allowances for all except the first eligible child in each family the net cost would be £55 million a year. The corresponding figures for a scheme confined in the main to the classes in the population which are already subject to compulsory national insurance would be £117 million and £52 million.

It would be unfortunate if we missed this opportunity of introducing a long-overdue reform. It might be well to start modestly with a scheme covering every eligible child except the first in each family, but to make it universally applicable since, if we can accept the above figures as reasonably accurate, the difference in cost between the universal and the limited scheme is relatively so slight. This would be of help to all except the smallest families. Eugenists would like also to give additional encouragement to families with the best heredity, but to discover the 'best' in this sense and to define it for administrative purposes would be difficult.

RECENT WORK ON GERMINATION

OPENING a discussion on seed germination held at the Linnean Society on May 14, Dr. M. A. H. Tincker, of the Royal Horticultural Society's Gardens, Wisley, read a paper dealing with the physiology of germination and incorporating some hitherto unpublished data of germination studies made at Wisley. The importance of low-temperature storage with low relative humidity tested in the United States was illustrated by common vegetable seeds including onion, carrot, leek and tomato. The response of seeds or achenes to various 'stratification' periods and temperatures so fully worked out at the Boyce Thompson Institute was also brought under review. With a number of lilies the seedling roots may grow but the shoots of certain species frequently do not appear for a year or more; while a higher temperature favours root growth, the dormancy of the epicotyl may be terminated by exposure to lower temperatures for a month or two. The seeds of further species of Primula have been shown to be light sensitive. Vernalization studies made at the Imperial College, in which very small embryos may grow into large plants almost as rapidly as normal grain, have an important bearing upon the question of small and large seed. The conditions favourable to the growth of small embryos in Fraxinus were mentioned, as was the widely different behaviour of the acorns of different oak species in regard to their after-ripening requirements in contrast to their similarity in respiration during winter. The interesting artificial methods used in Java of division of young, valuable seedlings of rubber at an early stage of germination to give a greater number of plants were described.

Mr. T. Hay referred to the germination of Emmenanthe (whispering bells) in soil which has been heated. *Romneya coulteri* also germinated better in heated soil. He stated that *Grevillea robusta* seed when placed in soil edgewise gave a higher germination than when flat. He mentioned the great difficulty experienced in raising many Cypripediums and the failure of imported seed. Referring to temperature conditions he cited Nemesia as germinating better at low temperatures despite its origin, and in regard to age and maturity preferred two-year-old leek seed and stated that old seed of stocks gave a higher proportion of doubles. He concluded by recounting the interesting story of the re-introduction of *Lathyrus magellanicus* by seed.



NELUMBIUM FROM THE SLOANE COLLECTION.
Placed in water, after removal of seed-coat, at 5 p.m. on May 12, 1942. Temp. 32° C. At 2 p.m. on May 13, ½in. long. Kept at room temperature afterwards and photographed on May 17, at 10 a.m.

Mr. G. W. Robinson remarked upon the slow germination of Hellebore seed often after 3–4 years from date of sowing, and commented on the Primulas, some of which proved troublesome. High temperatures in bush fires, well known to cause germination in Acacia spp., were observed in South America by him to cause *Sisyrinchium striatum* to germinate readily. Seed some eighty years old of Cytisus, Melilotus and other species had been successfully germinated.

Dr. J. Ramsbottom exhibited seedlings of *Albizzia Julibrissin* and Nelumbium. The seeds of the Albizzia were collected during Sir George Staunton's mission to China in 1793 and then stored in the Department of Botany at the British Museum. Following the fire in the Department at South Kensington due to an air raid in September 1940, the seeds became damp and when they were examined in November, were found to have germinated. Three of the seedlings were planted, and grown on at Chelsea Physic Garden; only one, however, survived the air attacks of May 1941. The main interest is that the seeds germinated 'spontaneously' after their 147 years storage.

Three Nelumbium seedlings were shown. Two of these were grown from fruits ('seeds') found in the prehistoric peat bed in the Pulantien Basin, South Manchuria: they are "probably at least three or four hundred years old". The seeds were presented to the Museum by Prof. I. Ohga in 1926; at that time in his experiments they showed a very high percentage of germination. The seeds, after the removal of their seed coats, germinated in water at 32° C., one after twenty-one hours, the other by the following morning. The third seedling was grown from a 'seed' taken from a receptacle in the Sloane collections. Robert Brown during 1843–1855 succeeded in obtaining twelve seedlings from fourteen of these seeds. As they were then not less than 150 years old this has stood as the record for longevity of seeds of known origin: Ohga tried twelve seeds in 1926 but none germinated though one seed, on being opened, showed green cotyledons. Only one seed was tried and within twenty-one hours it produced an outgrowth half an inch in length which had increased to more than an inch before the end of the second day. The Sloane Catalogue cannot be consulted conveniently at present so no exact data are available, but eighty-seven years have elapsed since the last of Robert Brown's classical experiments. The most surprising fact about the germination is the immediate rapid and rampant growth after a dormancy of centuries.

Mr. C. P. Raffill dealt with difficulties experienced in seed importation, stating that only 10 per cent of the seed importations into Kew gave satisfactory germination. He had experienced the greatest difficulty with seeds from Malaya, South America, East Australia, and East and West Africa and Ceylon. Magnolia seed from China and the Himalayan region failed when imported dry, but when kept moist by moss some germination was obtained. The seed of Michelia and related plants proved short-lived. Many plants from New Zealand (including Araliaceæ) produced seed which apparently died on drying; seed of Nothofagus also was imported successfully in damp storage but unsuccessfully when dried. Reference was made to the small degree of success obtained with the seeds of many tropical fruits.

In a brief reply Dr. M. A. H. Tincker referred to the availability of rapid means of transport by air and of modern methods of temperature control which should be tested for seed importation.

ELECTRICITY OF CLOUD AND RAIN

By DR. J. ALAN CHALMERS
University of Durham

IN his recent presidential address to the Royal Meteorological Society, under the above title, Sir George Simpson[1] has given a full account of experimental results on the processes giving rise to electrical charges on raindrops and in clouds. Due largely to work in which Sir George has himself taken a big part, a fairly clear picture is now available of the electrical structure of a thunder-cloud, showing a positive charge above and a negative charge below, with a localized concentration of positive charge at a still lower level. There must be two processes of separation of charge: an upper one, in a region where the temperature is below freezing-point, and where the separation has been ascribed by Simpson and Scrase[2] to a process of friction between ice-particles, giving a negative charge to the larger particles and a positive charge to the air; and a lower one, where the precipitation is entirely in liquid form, and where the separation of charge is ascribed to the breaking of drops, giving positive drops and a negative charge to the air.

But, as Sir George Simpson points out, the electrical phenomena associated with continuous rain, such as that preceding a warm front, are by no means so clearly understood. Although the meteorological conditions are probably less complex than in a thunder-cloud, the electrical manifestations are much less intense; and technique, such as that of the alti-electrograph, which is available for the investigation of thunder-clouds, is not sufficiently sensitive for the purpose of investigating clouds of the nimbo-stratus type responsible for continuous rain.

The investigation of electrical phenomena due to continuous rain clouds has been mainly confined to the measurement of the charges on the rain and of the vertical potential gradient at the earth's surface. It has been generally found that the charge on the rain is predominantly positive, while the potential gradient is usually negative; the correlation between the two has been established in the case of long-continued gentle rain, in a record analysed by Chalmers and Little[3] and in records mentioned by Simpson[1].

The problem of the electricity in continuous rain and the clouds responsible for it amounts to the discussion of the production of positively charged rain and a negative potential gradient. The negative potential gradient must be due to a negative charge situated in the base of the cloud or below it.

Electrical Processes at Work

The fundamental problem in regard to the electricity of continuous rain is one which can be stated in a number of different forms, now seen to be equivalent. In its simplest form it is as set out by Simpson[1], namely, the question as to how the rain gets its positive charge. There are two known processes by which water drops could obtain a positive charge under conditions of the kind under discussion: there is the process of the breaking of drops put forward by Simpson[4], which is recognized as responsible for the positive charge in the base of the thunder-cloud; and there is the 'influence' process suggested by Wilson[5] and verified in laboratory experiments by Gott[6].

The breaking-drop process leaves a negative charge in the air, and this will give rise to the negative potential gradient directly. On the other hand, if the influence process gives a positive charge to the drops, there must first be a negative potential gradient below the cloud, due to a negative charge in the base of the cloud. If, within the cloud, there is the same process of ice-friction which operates in the thunder-cloud, this will give the requisite negative potential gradient.

The two processes which could give rise to the charges on raindrops are sharply distinguished in regard to the origin of the charges in the cloud and the consequent negative potential gradient. The breaking-drop process will, in itself, give rise to a negative charge in the cloud, and there will be no need for any positive charge to be assumed in the cloud. On the other hand, the influence process requires a 'bipolar' cloud, with negative charge below.

In the breaking-drop theory, the primary result of the process is the positive rain, the negative potential gradient being a consequence of this; whereas in the other process, the first effect must be the production of a bipolar cloud, with negative potential gradient beneath, the positive rain arising from this by the influence process.

It is, of course, possible that both processes occur in the same cloud, as is the case in a thunder-cloud; then the negative charge in the base of the cloud may be partly due to the charge in the air from the breaking of drops and partly due to the process which gives a bipolar cloud.

Vertical Electrical Currents

The problem can be regarded in a different way if we make use of the important fact that conditions within and near a cloud giving continuous rain are quite steady; therefore whatever electrical processes may occur will probably not give rise to any marked changes in the distribution of electricity and give no added accumulations of charge. Thus we have the general principle that, for any one cloud, the total vertical electric current density must be nearly the same at all levels and so the same above, within or below the cloud; if we can determine the current density at any one level we know, approximately, its value at other levels. In particular, if by any argument we can determine the sign of the current density at any one level we know the sign at other levels. The vertical electric current is composed of the current carried by the rain, the conduction current and any convection current due to space charges carried up by vertical air currents.

Currents above the Cloud. It is perhaps simplest to discuss the vertical electric current density above the cloud, where the only current must be a conduction current between the ionosphere and the top of the cloud. If the cloud is bipolar, the potential of the top of the cloud may be higher than that of the ionosphere and hence there will be a negative current downwards. On the other hand, if the cloud is negative, the downward conduction current above the cloud will be positive. It is to be expected that the ions comprising the conduction current will originate in the ionosphere rather than in the cloud, and therefore the results of Wigand[7], who used a balloon to make measurements of conductivity above a stratiform cloud, are important. Wigand found the conductivity to be mainly due to negative ions, which is in agreement with the idea of a bipolar cloud, rather than a negative cloud.

Current within the Cloud. It can be seen that the same results occur if we consider the processes of separation within the cloud. In the formation and maintenance of a bipolar cloud, the process of separation gives a negative current downwards, as also occurs above the cloud; while in the breaking-drop process there is a positive current downwards. In the case where both processes occur in the same cloud, the upper process may produce charged drops which fall to the level where the lower process occurs, but there can be little effect of the lower process at the higher level, so that the resultant vertical electric current will be negative downwards.

Current below the Cloud. Below the cloud the vertical electric current consists mainly of the rain current carrying positive charge downwards and the conduction current carrying positive charge upwards. The sign of the resultant current therefore depends on the relative magnitudes of these two currents. Whereas the rain current can easily be measured, the conduction current is largely due to point-discharge, and though this can be measured for a single point, it can only be converted into a current density by assuming the separation of points equivalent to the one used; this has been discussed by Chalmers and Little[3] and by Chalmers[8]. If there is a bipolar cloud, the conduction current must be greater than the rain current, to give a resultant negative current downwards, while if there is a negative cloud the rain current is the greater.

Wigand's balloon measurements of conductivity below the cloud show a predominance of positive conductivity, as would be expected from the positive ions produced by point discharge.

Results for Snow

Since the breaking-drop process, and probably also Wilson's influence process, are effective for water in the liquid state only and not in the solid state, we should expect the results for snow to differ from those for rain. Simpson[1] has pointed out that the potential gradients during snowfall show no significant difference from those during rainfall; this indicates that the process responsible for the potential gradient does not depend on the presence of liquid water, and so cannot be the breaking-drop process, but must, presumably, be a process within the cloud below the freezing-point, for example, the ice-friction process. There seems a general consensus of experimental evidence that continuously falling snow carries a negative charge, and this is what we should expect if there is a bipolar cloud and no influence process by which the negative charge on particles from its base is lost and positive acquired. The results for snow are in agreement with the idea of a bipolar cloud, giving rise to a negative potential gradient, which, when there are raindrops, makes these positive by Wilson's influence process.

Eiffel Tower Observations

Chauveau[9] has given an account of observations undertaken at the Eiffel Tower which are of importance in connexion with the present discussion. Chauveau found that, frequently during continuous rain, the potential gradient at the top of the Eiffel Tower remains positive, though less than its fine-weather value, while that at the foot of the Tower is negative. As can be seen by drawing lines of force, the only interpretation of this, as the Tower is a conductor, is that the atmosphere between the levels of the top and foot of the Tower carries a negative charge. Since this would quickly be dissipated by conduction currents, there must be some process at work which provides a negative charge at this level but leaves no positive charge within the atmosphere; the breaking-drop process operating near the earth's surface would account for these results very simply, giving also the positive charge found on the rain.

It seems difficult to reconcile these results with those for snow, since in the absence of the breaking-drop process we should expect matters to be the same at the foot of the Tower as at the top, that is, with a reduced positive potential gradient rather than a negative. It is also difficult to reconcile these results with the predominantly positive conductivity below clouds found by Wigand.

Conclusion

Apart from the Eiffel Tower observations, the general trend of the results for continuous rain suggest that there is a process of separation of charge within the cloud, such as the ice-friction process, giving a negative potential gradient, and the raindrops falling in this potential gradient acquire a positive charge as described in Wilson's theory. Calculations showing the orders of magnitude of the currents and potential gradients have been given by Chalmers and Little[3]. In order to give an account also of the Eiffel Tower observations, we might add the breaking-drop process occurring near the earth's surface, but difficulties and anomalies remain, and it may be that conditions near the Eiffel Tower are peculiar.

A great deal remains to be done to confirm or disprove the ideas described above; among investigations that would be profitable may be suggested the measurement of rain currents and potential gradients under conditions similar to those of the Eiffel Tower, the measurement of rain currents and point-discharge currents using as discharger one of the trees of a plantation of similar trees, the measurement of potential gradients at various heights with a more sensitive alti-electrograph, and the repetition of Wigand's measurements when rain currents and potential gradients are simultaneously measured.

OBITUARIES

Prof. B. Malinowski

ANTHROPOLOGY has suffered a great loss by the death of Prof. Bronislaw Kasper Malinowski at Yale on May 16. Holding an international reputation in his field, he was a scientific worker with a subtle and constructive theoretical mind, a teacher who was stimulating to the highest degree, and a man of striking and in many ways most attractive personality.

Born on April 7, 1884, in Poland, Malinowski was first educated at the King Jan Sobieski Public School and later at the University of Cracow, where he graduated Ph.D. *summa cum laude* in 1908. Intending to do research work in physical science, he was prevented by the ill-health which interfered with his work all his life, and later turned to the social sciences, which he studied for a while at Leipzig under Karl Bücher. In 1910 he came to England, and as a student of the late C. G. Seligman began that long association with the London School of Economics and with British anthropology which proved so fruitful for the science he adopted.

At the London School of Economics he became a lecturer in 1913, but went with the Robert Mond Anthropological Expedition to New Guinea in 1914, and carried out field-work there, with intervals in Australia, until 1919. Returning to Europe in 1920, he again took up a post at the London School of Economics in 1921, and remained a member of the staff until his death, being appointed to the newly created chair of anthropology in the University of London in 1927. His links with the United States of America, however, had been many since his first visit there in 1926 at the invitation of the Laura Spelman Rockefeller Memorial. In 1936 the degree of Honorary D.Sc. was conferred upon him by Harvard University, and in 1939 while on leave in America he participated in the teaching at the Department of Anthropology at Yale University, where he became Bernice P. Bishop visiting professor for 1941–42.

As a writer and teacher Malinowski had a profound influence on the development of anthropological thought and research, not only in Great Britain but also abroad. He was not a systematist, and had little interest in the minutiæ of comparative investigation; he attacked, often wittily and sometimes violently, work of historical reconstruction on one hand and of pure technological analysis on the other. But to social anthropology, which he regarded simply as a branch of sociology, he contributed extensively both in methods of research and in fundamental generalizations. His name will always be associated with the "Functional Method", which however much it owed to Durkheim and the school of *L'Année Sociologique*, was by Malinowski re-formulated, developed, christened (complete with capitals) and forged into a powerful instrument for the analysis of cultural relationships and as a basis for a technique of field research. In its broadest sense indeed, under Malinowski's skilful handling, it became not merely a method of studying social phenomena but also an integrative set of generalizations about them and their inter-relations, based upon assumptions about the fundamental drives to human behaviour—in short, it was almost a philosophy of human culture. As such, it invited criticism while it spurred to further investigations. It also awoke interest in circles far beyond those of anthropology alone, bringing into touch studies of social institutions, of political organization, of religion, of technology, and of language.

The stimulus of Malinowski's writings and teaching was manifold. Not since Sir James Frazer has any other anthropologist in Great Britain so struck the imagination of a wide range of readers both here and abroad, by the combination of a vivid rich style, a breadth of treatment and a dramatic subject-matter. His first considerable work, "Argonauts of the Western Pacific", treating of the elaborate ceremonial exchange system of the Trobriand Islanders, and their magic rites, appeared in 1922. This was followed by "Crime and Custom in Savage Society", and "Myth in Primitive Society", in 1926; and "The Father in Primitive Psychology", and "Sex and Repression in Savage Society", in 1927, all based on his long period of intensive research in the same area. In 1929 appeared his best-known work, "The Sexual Life of Savages in North-western Melanesia". His last major publication, "Coral Gardens and Their Magic", appeared in two volumes in 1935. This, less widely read than the other books, is unexampled in its detailed analysis of a primitive agricultural system and its associated ritual; moreover, it contains an elaborate exposition of his theory of meaning in language, especially in magical language, a subject in which he had always a keen interest and to which he made a notable contribution.

As a teacher Malinowski was brilliant, giving of himself unsparingly, and treating his class not as pupils but as co-workers. More and more in later years he tended to abandon the formal lecture for a free discussion in the Socratic style, enlivening it by his flashing wit, and driving home a point in any one of half a dozen European languages to suit the members of the cosmopolitan group usually assembled around him.

But Malinowski's interests were not purely academic. He firmly believed that the test of a science in the last resort is its applicability to practical affairs. He tackled the problem in a systematic way, and in his training of government officials and missionaries and in his work for the International Institute of African Languages and Cultures, and the British Social Hygiene Council, he was one of the first to demonstrate the value of applied anthropology for Colonial affairs.

In all this, his gifts as a scientific worker and a teacher were closely bound up with his personality. To his powerful intellect were allied a great breadth of culture and charm of manner. His emotional hypersensitivity sometimes led him to harsh judgments of men and their motives, but his acute sense of values, his fundamental lack of affectation and his real humanity made his friendship a privilege and gave a richness to all his personal contacts.

RAYMOND FIRTH.

Prof. H. L. Bowman

DR. HERBERT LISTER BOWMAN, who retired from the chair of mineralogy at Oxford in July 1941, died unexpectedly in a nursing home at Oxford on April 22 at the age of sixty-eight.

Born on March 15, 1874, Bowman was educated at Eton College and New College, Oxford, where he took the Final Honour Schools of Natural Science in chemistry in 1895 and in physics in 1896, and proceeded to his M.A. in 1895 and to the D.Sc. degree in 1908. He became attracted to the study of minerals through the teaching of Prof. (now Sir) Henry A. Miers, who had been appointed professor of mineralogy in 1895 in succession to M. H. N. Storey Maskelyne, who had occupied the chair for thirty-nine years.

During the latter part of 1896 and in 1897 Bowman was engaged in research work and also devoted much time to helping in the rearrangement and registration of the mineral collection and in the development of several special exhibits in the Oxford Museum. In 1898 he went to Munich to study under Prof. Groth, and after spending eight months there and in visiting famous mineral collections in Germany and Austria, he returned to Oxford and was appointed demonstrator in mineralogy. During these years he also gave much help in the development and equipment of the Mineral Department at Oxford, which had no laboratory accommodation previous to 1895, and throughout his life he devoted much thought and time in this direction. Bowman was appointed Waynflete professor of mineralogy early in 1909 in succession to Prof. Miers, the appointment carrying with it a fellowship at Magdalen College. The title was altered in 1927 to include crystallography in recognition of the importance of that subject.

Bowman was a very painstaking and accurate research worker and teacher, and those who studied under him will remember his kindness and his patience and the help and advice which he always gave so readily. Most of his published researches deal with the chemical and physical properties of minerals and their modes of occurrence and were published in the *Mineralogical Magazine*, and his keen interest in meteorites is shown in the detailed examination of the Chandakapur and Dokáchi stones which he carried out in collaboration with H. E. Clarke and the results of which are contained in two papers also published in the *Mineralogical Magazine*. He also undertook the revision for the second edition of the standard text-book Miers' "Mineralogy" which was published in 1929.

An ardent collector of minerals, Bowman took part in Oxford expeditions to many English mineral localities, went with the British Association to South Africa and the International Geological Congress to Canada and Sweden. He also visited Switzerland annually for many years, and the Oxford collection is the richer by many specimens collected and presented by him. He inherited a keen interest in music and botany from his father, Mr. J. H. Bowman of Greenham Common, Newbury, and Dr. and Mrs. Bowman had been enthusiastic members of the Oxford Orchestral Society for many years. He also had great mechanical ability, and during the War of 1914–18 he did munition work in Birmingham. He devoted much time and thought to the designing and improvement of apparatus used in his department and introduced many novel experiments into his lectures.

To those who did not know him well, Bowman may have seemed reserved and shy, but he was an extremely kind and unselfish man, always ready to discuss problems and difficulties, and those who knew him intimately will remember him with great affection. He undertook many administrative duties at different times; thus he had served as Recorder of the Geological Section of the British Association, secretary to the Delegates of the University Museum, Oxford, vice-president of Magdalen College and of the Mineralogical Society. This left him little time for research work, but it was his intention, following his retirement, to take up active research again in his old department; his untimely death is a sad blow to his many friends.

In 1921 he married Pleasance Edith, daughter of Mr. James Walker of Kempsey, Worcester (under whom he studied physics in the Clarendon Laboratory at Oxford), and their married life was one of ideal companionship and perfect happiness.

R. C. SPILLER.

IT has been announced that among the Czechoslovak patriots recently executed by the Germans are a university dean and two professors, several secondary schoolmasters and a number of young men described as university students, although the universities have been closed for nearly two years. One of the professors was Prof. Jaromir Šamal, formerly professor of entomology in the Prague College of Agriculture, whose work had considerable local importance through his books in Czech on the anatomy and life-history of insects, on their ecology and their economic importance; Dr. Šamal was forty-one years of age.

WE regret to announce the following deaths:

Captain J. D. S. Pendlebury, formerly curator of Knossos and author of works on the archæology of Crete and Egypt, during the invasion of Crete in 1941, aged thirty-six.

Dr. George A. Reisner, professor of Egyptology at Harvard and curator of the Egyptian Department of the Boston Museum of Fine Arts, on June 6, aged seventy-four.

Prof. James Joseph Walsh, professor of physiological psychology at Cathedral College, New York, and medical director of the School of Sociology at Fordham University, aged seventy-seven.

NEWS and VIEWS

The U.S.S.R. Academy of Sciences and the Royal Society

IN response to a message from the Academy of Sciences of the U.S.S.R., Sir Henry Dale has sent the following reply on behalf of the Royal Society: "The Royal Society of London welcomes the inspiring appeal to the scientists of Britain, made by the members of the Soviet Academy of Sciences at their May conference. We appreciate the great honour bestowed on our President, Sir Henry Dale, and Prof. J. B. S. Haldane, by their election as honorary members of your Academy. The holding of the conference of your Academy at Sverdlovsk is symbolic of the scientific and technical progress made in the newly developed regions of the Soviet Union. We congratulate you on this mobilization of your prodigious resources, which encourages your friends and bodes ill for our enemies. The achievements of your scientists in all fields of research are followed by us with the liveliest admiration. The superb efforts of your countrymen in their resistance to the aggressor would have been impossible, if your technical resources had not been based on a great development of abstract science.

"British scientists likewise have made contribution to the common cause. There has been a growing application of scientific principles to our war effort, and, indeed, to all aspects of our national life. One result of this is to be seen in the remarkably high standard of the health of our people, in spite of ruthless air attacks upon our citizens, and other conditions which might have brought disease. Research has enabled the engineering industry of Britain to make immense advances since the War began. Agricultural research has played its part in reducing the shipping required for the transport of food, and thus releasing more to carry arms and munitions to the Soviet Union. Many inventions made by British scientists have been of decisive importance for the War, such as radio-location, and the device which rendered harmless the magnetic mine. We agree profoundly with you, in the belief that all our technical and scientific resources should be used to the utmost in this War to preserve liberty and democracy. Only thus, as you say, can science itself be saved, and resume its beneficent tasks on behalf of all mankind. Our most earnest and heartfelt hopes are with you in the present and the coming battles, upon the outcome of which the course of history for our countries and for the whole world depends."

Exchange of Scientific Information with the U.S.S.R.

MEN of science in Great Britain now have the opportunity of exchanging scientific communications and inquiries with the U.S.S.R. through official channels. A Conference was recently called at the Royal Society's rooms to discuss the development of contacts between British and Russian scientific workers. A Committee was appointed to examine the possibilities, and its work has been greatly facilitated by the sympathetic attitude of the Embassy of the U.S.S.R. The following procedure has been approved by the bodies concerned. Letters addressed by individual British men of science to individual Russian men of science, or communications from British scientific and technical societies to the corresponding Russian societies, can be forwarded either to: Sir John Russell, F.R.S., Ministry of Information, Malet Street, London, W.C.1, or Mr. J. G. Crowther, The British Council, 3, Hanover Street, London, W.C.1. They will take the necessary steps to forward the communications to the U.S.S.R.

Control of Cattle Diseases

A SCHEME for the control of certain diseases of cattle—mastitis, contagious abortion, sterility and Johne's disease—has been under the consideration of the Ministry of Agriculture for some time. It has the active support of the National Veterinary Medical Association of Great Britain and Ireland and of the National Farmers' Union, and it was brought into operation on June 1. The scheme is voluntary. Farmers wishing to participate are required to enter into an agreement. The Ministry of Agriculture provides free laboratory services for the diagnostic work, free vaccines for bovine brucellosis, and sulphanilamide at a reduced charge. The practising veterinary surgeon undertakes the work on the farm at fees that have been agreed upon. The National Veterinary Association has been pressing for action for some time and has prepared a report detailing the importance of these diseases and showing the extent of the losses they inflict upon the livestock industry in Great Britain. In terms of money, the losses from the first three of the diseases referred to above are estimated to amount to more than £17,000,000 a year. The annual loss of milk due to these three diseases alone (such a serious item in war-time) is estimated to be 198,000,000 gallons.

The position regarding bovine contagious abortion is discussed by F. Francis in the *Veterinary Record* of May 2 (p. 95). He describes the stages in which the essential knowledge of the bovine brucellosis problem has been built up. Much work has been done on the subject in many countries. In suitable circumstances the disease can be controlled by means of a serological test for evidence of infection and the adoption of measures to remove infected animals from the herds. The agglutination test is the most suitable one for this purpose, and it has been used on a large scale throughout the world. Small-scale attempts to control the disease in cattle have been made for more than thirty years and large numbers of herds have been cleared of infection. For this disease, however, the elimination of infection from individual herds is not sufficient; such herds are almost always surrounded by herds in which the organism is present, and they are in great danger of re-acquiring infection. The ideal would be to eradicate the disease on an 'area' basis until ultimately the whole country is cleared. A vast campaign to control bovine brucellosis on these lines has been in operation for some years in the United States and impressive results have been achieved, but it has been found to be costly.

Workers in the United States have developed a vaccine with 'strain 19' of *Br. abortus* which is of reduced virulence, but capable of conferring useful immunity. When young calves contract infection with *Br. abortus* after birth, they usually overcome it completely by the time they reach sexual maturity, and advantage has been taken of this phenomenon. 'Strain 19' has been used in the United States during the last few years for the vaccination of calves, and the reports show good results. McEwen in Great Britain has also developed and tested a strain of low virulence, 'strain 45 (20)'. In laboratory and field experiments he has found that vaccinated cattle acquire a serviceable immunity. The policy now adopted by the Ministry of Agriculture is to use these two vaccines in infected herds in an attempt to reduce the immediate losses. From June 1 no animal in a *TT* (tuberculin tested) herd shall be vaccinated with live *Br. abortus* except with the approval of the Ministry of Agriculture, and only with an approved vaccine. Two approved vaccines are issued by the Ministry of Agriculture, No. 1 (standard) vaccine, which is prepared from the American, 'strain 19', and No. 2 vaccine, which is prepared from 'strain 45 (20)'.

Health Contrasts in the United States

AN article in the March issue of the *Statistical Bulletin*, the organ of the Metropolitan Life Insurance Company of New York, discusses the difference in health in the United States during the War of 1914–18 compared with that in the present struggle, and comes to the conclusion that America is better prepared now for the hardships of modern warfare than twenty-five years ago. This is shown by the mortality among the industry policy holders of the Company, whose death-rate in the group 1–74 has been reduced slightly more than 50 per cent during the last quarter of a century. The diseases of childhood and infancy such as measles, whooping cough, scarlet fever, diphtheria, diarrhœa and enteritis have been virtually eliminated as causes of death during this period. There has been a considerable saving of life at this early age, and many young persons living to-day have been spared the disabling sequels of these diseases, so that thousands are now available for war service who would otherwise have been rejected. The death-rate from tuberculosis among the policy holders has been reduced by about one fifth. This is of great importance in connexion with the war effort, as many of the sufferers from tuberculosis are between the ages of twenty and fifty to which the great majority of the Fighting Forces belong. The mortality from syphilis, which occurs principally in youth and middle age and tends to increase in war-time, is less than half what it was in 1917. As regards influenza and pneumonia, which caused such heavy losses during 1914–18, the recent researches into the causal agent of the former are encouraging, while the latter, thanks to chemotherapy, has lost much of its terrors.

The increasing industrialization in the United States suggests that there may be an increase in fatal accidents in the near future, but the advance in industrial hygiene and prevention of accidents make it more likely that many lives and working days will be saved which under former conditions would have been lost. Improvement in pre-natal care, obstetric and hospital facilities is shown by the fact that whereas twenty-five years ago more than 17 out of every 100,000 policy holders died in childbirth, to-day this rate is reduced to 5. The great increase in motor accidents since 1917, due to the great increase in number of motor-vehicles, may possibly be mitigated by the curtailment of the supply of rubber and petrol.

Health of the United States Army

ACCORDING to the annual report of the Surgeon-General of the U.S. Army, summarized in the *Journal of the American Medical Association* of April 18, 257,136 men were reported sick from all causes in 1940, giving an annual rate per thousand of 763·3, an increase of 44 per cent over that of 1939, which was the lowest on record. The largest number of admissions was due to respiratory diseases. Then came infectious diseases and diseases of the digestive system. There were 267 admissions with 108 deaths due to aircraft accidents in 1940, and 32 deaths from accidental drowning. The admission for venereal diseases was 42·5 per thousand, and the number of days lost due to this cause 456,148. The average number of men absent from duty each day for venereal disease was 1,246 and the average length of treatment was 52 days. The average number of days lost for syphilis was 28, for gonorrhœa 35 and for other venereal diseases 20. During the year, 1·39 per cent of the strength of the army was lost by discharge or retirement for physical disability. Dementia præcox was the chief cause for discharge. Tuberculosis reached a new low level. There were 229 deaths attributed to motor accidents.

Electrically Driven Excavators

IN a paper given before the Institution of Electrical Engineers on May 14, P. H. R. Durand points out that the electrically equipped single-bucket excavator is employed extensively in the quarrying of rocks such as limestone and chalk for cement manufacture, ironstone and other minerals and also for excavating granite, sand and gravel, clays and shales. Large installations are used in the open-cast mining of coal. These machines are also used sometimes around industrial works for handling materials such as blast-furnace slag. In some quarries the excavator provides raw material which is processed in an adjoining factory and for which there may be limited accommodation prior to processing. The excavator is here the starting-point of a mass-production unit, its rate of output being measured by the hour instead of by the week or month, and in applications of this type it must be regarded as an automatic machine. The author describes the sphere of application of the excavators and, in commenting on the increasing importance of electric drive, gives an explanation of the fundamental motions and structural limitations of the machines.

A summary of the special service conditions precedes a discussion on electric drive methods for the two main groups of excavators, the 'friction' type and the individual-drive machine, where the application of the modern Ward-Leonard system with 3-coil dynamo and separately excited motor is referred to in some detail. Main and auxiliary equipment is described from the electrical and mechanical aspects, and installation and wiring details are supplemented by illustrations of typical equipment layouts and wiring diagrams. Attention is directed to certain special aspects of power supply and distribution to excavating projects, representative power consumptions being given. The scope of the paper is limited by present circumstances, no reference being made to Continental or overseas practice, or to the dipper dredge, which, possessing an operating cycle similar to that of shovel excavators, is equipped with motors and control of equivalent characteristics. Illustrations are confined to the smaller machines, since up to the present time the scope of excavating operations in Great Britain has not stimulated any demand for the larger machines except for stripping shovels to remove deep overburden in the ironstone mines.

Prevention of Blindness

THE March issue of the *Boletin de la Oficina Sanitaria Panamericana* gives the following list of international societies for the prevention of blindness: The International Society for the Prophylaxis of Blindness was organized in 1929 under the presidency of the late Dr. Félix de Lapersonne, professor of ophthalmology in the Paris Medical Faculty, and held several meetings in various European capitals, the last being in Cairo in December 1937 in conjunction with the Fifteenth International Congress of Ophthalmology. Its office is at 66 Boulevard St Michel, Paris 6^e. In 1930 it became united with the International Organization for the Campaign against Trachoma, the organ of which is the *Revue internationale de Trachome*. Other international societies of the kind are the International Association for Blind Students, 1 Rue Etienne Dumont, Geneva, and the Spanish-American Association for the Blind, 1545 Madison Avenue, New York. Reference may also be made to the International Council of Ophthalmology, Rotterdam, and the International Federation of Ophthalmologic Societies.

Bibliography of Seismology

THE *Bibliography of Seismology* for the period July–December 1941, prepared at the Dominion Observatory, Ottawa, by Mr. Ernest A. Hodgson (now president of the Seismological Society of America), has just been received. It covers 145 items, ranging through pure and applied seismology, building construction, cosmogony, engineering, instruments, insurance, oceanography and time-keeping. About forty-five items deal with seismic prospecting and patents associated with it, and forty-two items deal with instruments, chiefly for the detection of various types of natural and artificial seismic waves. Items in NATURE are listed. Several items deal with seismic surveying in the U.S.S.R. (for example, "Prospects of Seismic Survey by the Method of Refracted Waves in the Region of Ust-Eniseisk Port" by R. M. Demenitskaia, Problemi Arktiki, No. 5, 81–92, Leningrad, 1939), and it is not known whether or not the War has interfered with many of these projects. From time to time luminous phenomena have been reported as accompanying seismic phenomena, and one such is listed: "Sur les phénomènes lumineux qui ont accompagné le tremblement de terre de Roumanie du 10 novembre 1940", G. Demetrescu and G. Petrescu, Académie Roumaine, Bulletin de la Section Scientifique, Tome 23, No. 6, pp. 5, 1 chart, Jan., 1941."

"Thorpe's Dictionary of Applied Chemistry"

FIVE volumes of the current edition of "Thorpe's Dictionary of Applied Chemistry" were published under the editorship of Sir Jocelyn Thorpe and Dr. Martha A. Whiteley. With the death of Sir Jocelyn Thorpe new editorial arrangements have been necessary, and in order to maintain a balance between the various branches of chemical science, an editorial board has been formed, comprising Prof. I. M. Heilbron (professor of organic chemistry and director of the Laboratories for Organic Chemistry at the Imperial College) (chairman), Prof. H. J. Emeleus (assistant professor and reader in inorganic chemistry at the Imperial College), Prof. H. W. Melville (professor of chemistry in the University of Aberdeen), and Prof. A. R. Todd (Sir Samuel Hall professor of chemistry and director of the Chemical Laboratories in the University of Manchester). This Board will determine the general editorial policy in conjunction with the publishers. Dr. Whiteley continues as editor, and Dr. A. J. E. Welch (assistant lecturer in inorganic chemistry at the Imperial College) becomes assistant editor; thus the association with the Imperial College is being maintained. Vol. 6 of the current edition is in the press, and it is proposed to complete the edition with eight further volumes, published at yearly intervals. Although the Board does not consider that any major modification of the general character of the work is required, certain changes in the scope of the articles, particularly with regard to physical chemistry topics, are to be made.

Announcements

THE University of Marburg, with the support of the Behring Works, has founded an Emil von Behring prize consisting of a medal and a sum of five thousand gold marks. It will be awarded every two years for scientific work in medicine, veterinary medicine or natural science, with special reference to immunity and control of epidemics.

UNDER the title "Why I am a Rationalist: Books which have Influenced Me", Messrs. C. A. Watts and Co., Ltd., have published for the Rationalist Press Association, Ltd., a series of autobiographical essays which originally appeared in the "Literary Guide". The contributors include the Right Hon. Lord Snell, Prof. J. B. S. Haldane, Marjorie Bowen, Prof. H. Levy, Ivor Brown, W. B. Curry, and others. The contributions are of varied merit but form a useful, if scarcely critical, guide to a wider range of literature than can fairly be claimed by rationalism as its own. The book may well direct readers to books which to-day do not receive the attention they deserve.

THE tenth annual Summer Conference on Spectroscopy and Its Applications, arranged jointly by the Optical Society of America and the Massachusetts Institute of Technology, will be held at the latter during July 20–22. A symposium on fluorescence and phosphorescence is planned in connexion with the Conference. Admittance to the Conference will be by reservation as usual. Further information and tickets can be obtained from Prof. George R. Harrison, Massachusetts Institute of Technology, Cambridge, Massachusetts. The usual courses in spectroscopy will not be given at the Massachusetts Institute of Technology this summer.

Prof. M. Polanyi and Mr. A. G. Evans write: We wish to supplement our letter entitled "Calculation of Steric Hindrance" (NATURE, May 30, p. 608) by the following footnote which was attached to the letter in proof, but was not received in time to be printed: The presence of steric hindrance in the case of neopentyl has been briefly pointed out by Hughes (*Trans. Far. Soc.*, 623; 1941) on what seem to be similar lines. He, however, interprets the slowness of reactions of the type (1) for *t*-butyl halides on a different basis. See also a recent paper by Bartlett and Rosen (*J. Amer. Chem. Soc.*, 64, 543; 1942) on steric hindrance in neopentyl halides.

LETTERS TO THE EDITORS

The Editors do not hold themselves responsible for opinions expressed by their correspondents. No notice is taken of anonymous communications.

Nutrition and the War

I WOULD like to thank Dr. Kon for his kind remarks about my book[1] in his review in NATURE[2], and for his critical comments, which, coming from a person of his standing in the nutritional world, are of considerable value to me. I would like, however, to comment on some of the statements which he has made.

On p. 82 of my book, immediately preceding the food tables, I state, "It will probably be noticed that peas, beans and lentils are good in almost every constituent, but it should be remembered that we eat relatively small quantities of them at a time so that in their case the appraisement may be a little misleading. In the case of potatoes, which are listed as poor in calories, they may constitute a significant proportion of one's calorific intake if enough of them is eaten." In view of this statement, I feel that Dr. Kon is unjust in his comment that there is "a lack of appreciation that it is not so much the richness of a product in any given food factor as the amount consumed that matters in the end".

Dr. Kon points out that this lack of appreciation has led to the "strange selection of curry powder as the best source of iron". McCance and Widdowson[3], to whom incidentally Dr. Kon refers me, state on p. 9 of their report, "Curry powder contained more than three times as much iron as any other food (75 mgm. per 100 gm.)". That curry powder is so rich in iron that the amount used in making a meat curry is sufficient to secure an important increase in the amount of iron eaten can be seen from the figures given below (McCance and Widdowson[3], p. 103).

Beef stew	..	2·49 mgm. of Fe per 100 gm.
Curried meat	..	4·70 ,, ,, ,, ,, ,, ,,

In the circumstances I do not agree with Dr. Kon that my selection of curry powder as the best source of iron is a strange one.

In mentioning my reference to the food value of ethyl alcohol, Dr. Kon refers to this "misinterpretation of Mitchell's work". I purposely made no attempt to interpret Mitchell's work and gave only a plain statement of fact. A comparison of the following two statements will make this clear:

From Mitchell's paper[4], p. 333. "The energy of ethyl alcohol is to a large extent available for physiological purposes. Added to a complete diet such as milk it induces more rapid growth and greater retention of nitrogen as well as fat."

From my book, p. 136. "Dr. H. H. Mitchell . . . found that rats fed on a diet adequate in the known nutritional factors and to which a small daily allowance of alcohol had been added, grew faster and retained fat and nitrogen to a much greater extent than other animals which received the diet without the alcohol."

---

(1) I STILL feel that, in a popular book on nutrition, great care should be exercised in giving the reader guidance on the best choice of practical sources of supply of different nutrients, and I still think that Dr. Bourne's tables do not give such guidance. The value of curry powder as a practical source of iron for the population of Great Britain is, in my opinion, nil.

(2) The food value of ethyl alcohol. Mitchell's experiment showed that when alcohol was added to a certain diet its energy was available for physiological purposes, but that it was only three quarters as available as that of a similar supplement of sugar, which caused greater retentions of nitrogen and energy. Dr. Bourne's description makes no mention of the comparison of alcohol and sugar and conveys the impression that alcohol exerts a specific beneficial effect on the deposition of fat and utilization of food nitrogen. It tells the truth but not the whole truth, and in this way it certainly misinterprets Mitchell's findings.

Amino Acids and the Human Being

THE satisfaction which may quite legitimately be felt in the logical and painstaking work which enabled Rose to classify the amino acids into essential and non-essential groups rather dims the realization that his classification only refers to the needs of the growing rat. In his recent communication to NATURE, Mr. Bacharach[1] gives a welcome jolt to the complacent attitude, so easily adopted, of assuming that what is true of the growing rat is true not only of the adult rat, but also of other species of animals. The work of Wolf and Corley[2], and of Burroughs, Burroughs and Mitchell[3], has shown, however, that the amino acids required to maintain nitrogen equilibrium in the adult rat are not entirely the same as those needed to make the young rat grow. These results illustrate the necessity of qualifying the term 'essential' when it is applied to amino acids.

Although about six years have elapsed since Rose made his classification of amino acids into essential and non-essential groups, our knowledge of the requirements of other species of animals is distressingly meagre. The sum total of our knowledge appears to be that the adult dog probably requires the same amino acids as the adult rat for the maintenance of nitrogen equilibrium, that in the regeneration of plasma protein in dogs with experimental hypoproteinæmia, cystine, leucine and glutamic acid are of primary importance, that the chick requires tryptophane, histidine, methionine, and (most surprisingly) glycine for growth and arginine for both growth and maintenance, and that lysine is required by cattle for both maintenance and milk production. What other amino acids are required by the chick and by cattle have not been elucidated.

Mr. Bacharach points out that it would be interesting to know what evidence there is indicating the indispensability or dispensability of individual amino acids for humans. At the end of last year Holt and his co-workers[4] showed that human subjects on diets deficient in tryptophane or lysine develop negative nitrogen balances which can be restored to normal by supplying the specific amino acid. No other evidence of this nature exists so far as I am aware: indeed only Sharpenak and his colleagues[5] have hitherto shown any active interest in the question of the amino acid composition of human flesh, and of the combination of natural foodstuffs which would supply these amino acids in the required proportions. It is unfortunate that although more refined methods are now available for the determination of amino acids in proteins, no further work has been done on these lines.

Supplies of protein foods for both the human and the stock populations of Great Britain are limited, and this limitation will continue after the War. For the most economical use of these supplies it is obviously of the utmost importance for us to determine as rapidly as possible the qualitative and quantitative amino acid requirements of farm animals and man.

Ancestry of Captorhinomorph Reptiles

IN a review of Tetrapod origins[1] I have mentioned certain results of comparisons of early Reptilia and Amphibia of which a full account must await less abnormal circumstances. Meanwhile it seems desirable to outline some of the conclusions.

The Seymouriamorpha and Diadectomorpha, reptiles of Permian age, are often considered to include ancestors of the other reptilian groups. But the geological history of the Captorhinomorpha and their Pelycosaur relatives goes back well into the Stephanian[2], and Captorhinomorphs may possibly include also the ancestors of Diapsid reptiles. It is therefore of considerable interest that they cannot be derived from Seymouriamorphs, nor apparently from Diadectids.

The well-known Captorhinomorphs are comparatively late (Captorhinus, Labidosaurus are Clear Fork = Artinsk). They have very specialized temporal regions, and the bone nomenclature is controversial. But Pelycosaurs, which are certainly derived from early Captorhinomorphs, show a primitive condition (seen also in Diadectes, etc.) in which the supratemporal lies in the skull-table and meets the postorbital; the supratemporal also turns down to lie near the paroccipital process, from which it is separated by the tabular, here a bone of the occipital surface[2]. Comparison of the series Ophiacodon—Eothyris (both Pelycosaurs)[2]—Protorothyris—Romeria (both Captorhinomorphs approaching Pelycosaurs)[3]—Captorhinus shows that the supratemporal is easy to follow throughout. In Captorhinus it is the small flake on the skull-table, often called tabular; in Labidosaurus Williston shows the bone to be absent. In both forms the tabular, if present, must lie on the occipital surface. It is clear that the supratemporal is greatly reduced in the late Captorhinomorphs; early members should have had large supratemporals meeting the postorbitals, with tabulars and postparietals (= dermosupraoccipitals) on the occipital surface, and the otic notch largely obliterated by downward rotation of the paroccipital process, tabular and supratemporal. Such a type could be ancestral to known Captorhinomorphs and Pelycosaurs, and is in sharp contrast to Seymouriamorphs. The Diadectomorph structure is not dissimilar.

This primitive Captorhinomorph structure compares exactly with that of the uppermost Westphalian "Adelospondyl Amphibian" Microbrachis and its apparent relative Hyloplesion (which shows that the bone in Microbrachis called 'tabular' is the supratemporal[4]), and with no other known Amphibia. These forms show marked resemblance to Captorhinomorphs in the structure of the whole skull and palate, rather similar vertebræ, ossified caudal intercentra bearing hæmal arches (unossified intercentra may possibly have occurred elsewhere), somewhat similar arrangement of ribs, etc. The limb skeleton is not too well known in the Nýřany Microbrachids, where the hand is apparently reduced to three digits. The digital formulæ of the feet of Microbrachis and Hyloplesion are 2, 3, 4, 4, 3 and 2, 4, 5, 3, 1 respectively. It is clear that these forms are too specialized (degenerate ?) to be actual Captorhinomorph ancestors; but it is highly probable that the contemporaneous Linton (Ohio) forms *Tuditanus punctulatus* (Cope) (= *Eosauravus copei* Will.) and *Eusauropleura digitata* (Cope)[5] are closely related to them (they correspond well in other ascertainable characters to Microbrachids) and these show respectively the digital formulæ (foot), 2, 3, 4, 5, 4 and (hand) 2, 3, 4, 5, 3. Several other Microsauria show remarkably reptile-like characters, involving limb-girdles, vertebral structure, hæmal intercentra, presence of entepicondylar foramen in humerus, etc. (for example, Hylonomus, Fritschia)[6].

It seems very probable, therefore, that the ancestry of the Captorhinomorpha is to be sought among small Carboniferous vertebrates which Moodie would have included in his Microsauria and are now usually regarded as Adelospondyl or Lepospondyl Amphibia. (Recent experience has made the neurocentral suture an unreliable character for separating Adelospondyli and Lepospondyli[7].) Moodie, long ago, suggested that *all* reptilia originated from the Microsauria, a view held by others of the older workers, and Goodrich also noted reptilian characters in the caudal intercentra of Hylonomus, and regarded the Microsauria as reptiles. The remarkably annectant characters of Seymouria have diverted attention from the smaller forms, and Seymouria was certainly derived from Anthracosaurid Embolomeri[8]. Diadectes seems to be a somewhat isolated type, of which the ancestors cannot yet be indicated, though in many details it resembles Captorhinomorphs. The cranial pattern and general similarity of body structures show that Seymouriamorphs, Captorhinomorphs and Diadectomorphs could only be derived ultimately from Anthracosaur-like Stegocephalia. Pantylus, as suggested by Säve-Söderbergh, should be removed from Cotylosauria; I hope to comment further on this interesting form and its relatives.

The Cotylosauria may therefore be regarded as springing ultimately from a fairly well-defined stock, but the differentiation along at least two of the three main lines occurred while the animals were still technically Amphibia. Säve-Söderbergh's term Reptiliomorpha[9] is useful to cover the Anthracosaurs and the Cotylosaur groups, and should also include the smaller animals discussed above; some of the other Carboniferous smaller Amphibia (Nectidia, Aistopoda) may possibly be nearly related.

Mitotic Divisions following Meiosis in *Pediculus corporis* Males

MANY years ago one of us[1,2] found that the offspring of single-pair matings of the body louse, *Pediculus corporis*, are often all of one sex, and that even when both sexes are represented among the offspring of one pair there may be a significant preponderance in the numbers of one or the other sex. Data since collected have confirmed and extended these observations, and also shown that differential mortality does not account for these unusual sex ratios, but hitherto no satisfactory explanation has been found of the method of sex determination. During our attempts to find out the mechanism involved, the process of spermatogenesis has been reinvestigated, and the results obtained, although at present throwing no light on the main problem, seem of sufficient interest to be recorded.

In *P. corporis* the somatic cells of both sexes, and also the oogonia and spermatogonia, contain six pairs of extremely minute chromosomes. So far as can be seen, five pairs have a median, and one a terminal centromere. We have not been able to distinguish any dimorphic pair.

In the embryo meiosis starts before hatching and continues at least during all three nymphal stages; spermatogonial divisions can be seen throughout the same period. It will be understood from what follows why meiotic divisions, as well as spermatogonial divisions, are so rare as to have escaped notice by previous workers[3,4].

The spermatogonia ($2n = 12$) undergo meiosis singly without the preliminary growth-phase usually occurring in spermatocytes. There are five bivalents and two univalents in the first division. The second division, even more rarely seen than the first and therefore very rapid, in the metaphase plate shows six chromosomes, five arranged peripherally, and one in the centre. This arrangement is repeated in the five subsequent mitoses described below.

The four haploid products of meiosis, each much smaller than the original spermatogonium, undergo four successive mitotic divisions in perfect synchronization, forming successively cysts of 8, 16, 32 and 64 cells. After the 64-cell stage has been reached, a certain amount of growth takes place and a large spherical mitochondrial body makes its appearance. A fifth mitosis follows, of a very peculiar type, accurately described by Doncaster and Cannon[3,4]. One of the daughter nuclei with very little cytoplasm and no trace of the mitochondrial body is extruded at telophase; while the other daughter-nucleus, together with practically all the extra nuclear material, including the mitochondrial body, begins its transformation into a spermatozoon. Hence there are only 64 spermatozoa in each bundle.

It will be seen, therefore, that in Pediculus the phase of multiplication of the germ cells which usually precedes meiosis takes place in part after meiosis; in other words, meiosis is pushed back in the development of the germ track. So far as we are aware, the only comparable case known among the higher animals and plants is that of the haploid testes in the diploid hermaphrodite coccid, *Icerya purchasi*.

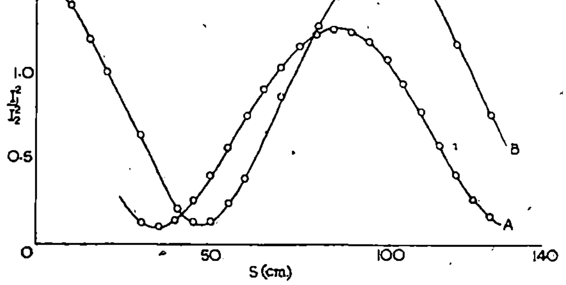
Input Impedances of Vacuum Thermo-junctions at Ultra-High Frequencies

THE method of analysing impedances at ultra-high frequencies using Lecher wires, recently described by Flint and Williams[1], has been used to examine a number of thermojunctions the D.C. heater resistances of which varied between 100 and 1,600 ohms. The frequency employed was approximately 150 Mc./sec.

The input impedances were measured with the junctions mounted in pin bases secured in valve-holders and also when demounted and connected directly to the Lecher wires. The latter method removed the substantial capacitative effect inherent in the external mounting, but left the capacities within the pinch and also the self-capacity and self-inductance of the spiral filament. At the above frequencies these residuals have an admittance comparable with that of the filament.

If the thermo-junction is used to terminate the transmission line, a change in its reactance will change the phase angle in the reflexion coefficient. This will be accompanied by a shift in the standing wave system which is set up.



The shift produced by demounting a junction (D.C. filament resistance, 1,500 ohms) is shown in the accompanying figure. Curve *A* was obtained with the junction mounted and curve *B* when demounted.

Calculations for the various junctions available are summarized in the table below. *R* denotes the D.C.

D.C. Resistance R (ohms)	H.F. Series Components				H.F. Parallel Components				M_p (pf)	N_p
	R_s (ohms)		X_s (ohms)		R_p (ohms)		X_p (ohms)			
	Mounted	Demounted	*M*	*D*	*M*	*D*	*M*	*D*		
90	105	—	+76	—	160	—	+ 221	—	—	—
410	414	540	−13·7	+ 69	414	549	−1250	+4300	1·03	4·6 μH.
1500	320	994	−439	−394	922	1150	− 673	−2900	1·21	0·36 pf
1600	335	1140	−432	−570	892	1425	− 692	−2850	1·16	0·37 pf

resistance of the filament; R_s and X_s are the series resistive and reactive components of the input impedance, while R_p and X_p are the equivalent parallel components; M_p denotes the capacity introduced by the mounting and N_p the net residual inductance or capacity of the demounted junction.

These results show:

(1) That the residuals in this type of junction are inductive for low values of R (X is positive), but are capacitative for the higher values (X is negative). This is believed to be a net effect with the self-capacity increasing more rapidly with the length of the spiral than does the self-inductance. Thus for the junctions of higher resistance this increased self-capacity more than nullifies the rise in the resistive component due to the skin effect and to the self-inductance. For these, R_p is less than the D.C. value.

(2) That the demounting of the junction corresponds to the removal of a shunt capacity of approximately 1·1 pf., leaving only the residuals.

They demonstrate, therefore, the importance of an individual analysis of a thermo-junction if it is to be successfully matched into any circuit.

The current responsible for heating the filament is a fraction of the total current through the junction assembly. This fraction depends on both the applied frequency and the construction of the junction, but our results indicate that it is independent of the magnitude of the current. The response of the junction at ultra-high frequencies is thus proportional to the D.C. calibration curve, which may, therefore, be used in the interpretation of radio-frequency currents. This calibration curve is rarely linear, so that for accuracy reference should always be made to it.

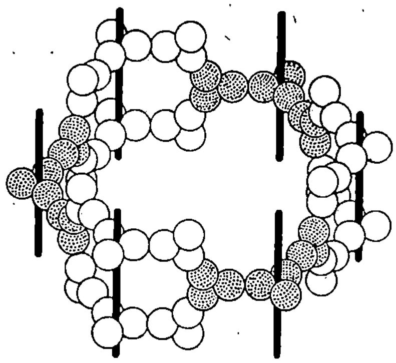
Open Packing of Spheres

TAKE four equal spheres with diameter d and place one at each vertex of an equilateral triangle the sides of which are $2d \cos 30°$ in length: the fourth sphere placed at the centre of the triangle will make contact with the first three. Call this set of four spheres a structural unit. Next draw a regular hexagon with sides $2{\cdot}5d$ in length. At alternate vertices of the hexagon place a structural unit with its centre coinciding with the vertex, and two lines of centres from the middle sphere coinciding with two sides of the hexagon. Construct a second sheet of units with their centres over the remaining vertices of the hexagon, corresponding lines of centres overlying the remaining sides of the hexagon. Add a third sheet the same as the first and overlying it: and a fourth the same as the second overlying the second, and so on.

In the resulting structure (which has a density of 0·149) the lines of centres from any sphere to those touching it make angles of 120°, and therefore Heesch and Laves's *Ersetzungsprinzip*[1] can be applied to it. This consists in substituting a group



of three spheres (in mutual contact) for every sphere in the original structure. In this way we arrive at the system shown in the accompanying figure. This structure has a density of 0·045 and a higher degree of homogeneity than that recently described[2].

Catalytic Dimerization of Isobutene by Activated Copper Sulphide

IN previous communications[1] it has been shown that copper sulphide, activated by oxidizing a part of its surface into copper sulphate, is a catalyst for the low molecular polymerization of isobutene. It has now been found that the main product of the catalytic process is a mixture of the two 2 : 2 : 4-trimethylpentenes which on hydrogenation were converted into 2 : 2 : 4-trimethylpentane. This latter compound was identified by determining the boiling point, the specific gravity, the refractive index, the melting point and the mixed melting point with an authentic sample. A detailed description of the experiments will be published elsewhere.

RESEARCH ITEMS

Fruitflies of the Genus Anastrepha

MISCELL. PUB. 839 of the United States Department of Agriculture (Washington: Govt. Printing Office. 40 cents) is devoted to the above subject. In about a hundred pages the author, Alan Stone, contributes a more or less complete systematic monograph on the genus in question. Certain of its species in their larval stages damage the fleshy parts of subtropical and tropical fruits of various kinds. Six species are at present recognized as being of major economic importance in the western hemisphere, where they damage such fruits as citrus, mango, guava, peach, etc. The range of the genus is from South America, into tropical Central America and the West Indies together with southern Florida; also a few species are Mexican. The author recognizes 126 presumably valid species, and in the accompanying key the females only are dealt with. The apex of the ovipositor is figured in many cases since it affords characters of recognized value. Difficulties, apparently insuperable at the present time, preclude the preparation of a similar key to the males. The early stages are not dealt with, since they are known for so few of the species.

Indian Fishes

IN a lecture delivered to the Royal Asiatic Society of Bengal on March 25, 1941 (*J. Roy. Asiatic Soc. Bengal,* Science, 6, Article No. 10; 1940), Sunder Lal Hora gives interesting information on the life-history and wanderings of Hilsa in Bengal waters. *Hilsa elisha,* allied to the herring, is a valuable marine fish the periodic ascent of which into fresh waters has earned it the name of the Indian shad. Dr. Hora has already published papers on his researches on the spawning grounds and bionomics of this fish (*Rec. Ind. Mus.*, 40, 42), but the present paper is valuable in bringing together in simple language all that is known, with comments on the fishery. It is only quite recently that it was found positively that Hilsa spawns high up in the rivers. A series of papers on fishes by the same author is published in the *Records of the Indian Museum* (43, Part II; 1941), in the *Journal of the Bombay Natural History Society* (42, No. 2; 1941) and the *Journal of the Royal Asiatic Society of Bengal,* Science, 6; 1940, 1941). These include descriptions of the freshwater fish of Travancore and a continuation of former work on the same fishes of India.

Intertidal Sand Fauna

E. EMRYS WATKIN ("The Macrofauna of the Intertidal Sand of Kames Bay, Millport, Buteshire" *Trans. Roy. Soc. Edinburgh,* 50, Part II, No. 16; 1942) has continued the studies carried on by Elmhurst and Stephen (1928–31) and now attempts a more precise statement of the zonation by fixing stations at much narrower intervals, actually 5 yards apart, giving 42 stations over a horizontal range of 210 yards, from high-water spring tides to low-water spring tides. The groups of animals represented are chiefly Crustacea and Polychæta and the very abundant lamellibranch *Tellina tenuis.* On the whole, the Crustacea are more sharply zoned than the Polychæta, with each species showing a more definite centre of abundance. Compared with other bays, the zonation is usually similar, although a few definite exceptions occur. Special attention is paid to the size of the soil particles, and a mechanical analysis is made of these which shows that the soil is very even over the whole tidal range, with particles of a size 0·2–0·5 mm. accounting for more than 80 per cent of the samples. Comparison with the analysis of soils by other workers shows that this composition carries high population densities. The author points out that the grade composition of the soil appears to affect density directly, but it cannot account to any extent for the zonation of the organisms, and the factors governing zonation are still problematical and differ from species to species.

Relative Firmness of Pig Back Depot Fat

IN a paper by W. Bolton and R. G. Baskett read at a meeting of the Society of Public and Other Analytical Chemists on May 6, the iodine value as an index of the relative firmness of pig back depot fat was considered. For pig back depot fat a close correlation was found to exist between the iodine value (Wijs) and the firmness as measured by means of the grease penetrometer of the Institute of Petroleum. The firmness measurements were carried out at 30·5°, 32·0° and 46·5° F., at which temperatures the average depths of penetration were 4·5, 6·4 and 15·3 mm. The correlation coefficients between iodine values and depths of penetration were + 0·9564 (23 samples) at 30·5°, + 0·8543 (28 samples) at 32·0°, and + 0·7136 (28 samples) at 46·5° F. In laboratories where the close temperature control necessary for penetrometer or similar direct tests of firmness are impracticable, the iodine value will give a more accurate measure of the firmness of these fats.

Temperature and Sex Ratio in *Drosophila pseudo-obscura*

MALES of *Drosophila pseudo-obscura* and several other species of Drosophila exhibit the genetical character 'sex-ratio' by giving more than 90 per cent females in their progeny, no matter what female is used as mate. C. D. Darlington and Th. Dobzhansky (*Proc. Nat. Acad. Sci.*, 28, 45; 1942) give evidence which suggests that the X-chromosomes in these males divide twice instead of once at meiosis. As a result the majority of the spermatids contain an X-chromosome. The abnormal behaviour induced by a gene appears to depend on an excessive charge of nucleic acid, and, therefore, the authors expected the effect could be influenced by temperature as in other organisms. They find that there is a significant increase of males in the progeny of males kept at 16° C. as compared with those kept at 25° C.

Rainfall in South Madras

SCIENTIFIC Note No. 98 of the India Meteorological Department by V. Doraiswamy Iyer is devoted to the forecasting of the north-east monsoon rainfall of the south of Madras by the methods developed by Walker and others. The south-east of India, which is agriculturally important, receives comparatively little rain in the main wet monsoon period, June–September, and gets the bulk of its annual fall during October, November and December, when the south-west monsoon is retreating from India and when the rain-bearing winds on the Coromandel coast are north-easterly winds that have passed round the seasonal low-pressure area south of the Bay of Bengal. The formulæ developed in this investigation were arrived at after preliminary studies of the correlation coefficients between the rainfall of these months in the different sub-divisions of the province of Madras had shown that the south-east of Madras and Malabar can usefully be combined into a single region for forecasting. The rainfall of this region, which may be called "South Madras" was then studied in relation to various meteorological elements at action centres in other parts of India and further afield, and the formula arrived at was:

> South Madras Rain = − 0·39 (S. America pressure June–Aug.) − 0·38 (Bangalore westerly winds at 3–5 km. height, Sept.) + 0·21 (Agra westerly winds at 5–8 km. height, Sept.)

This formula has a multiple correlation coefficient of 0·60. The formula for south-east Madras rainfall alone, using the same variables, was found to have only slightly different numerical factors, these being −0·38, −0·37 and +0·22, and, as was to be expected, the multiple correlation coefficient is nearly the same, being 0·59. Graphs of actual and calculated falls during 1914–1940 are given, followed by a discussion of the meteorological peculiarities of some of those seasons when the agreement between the two curves was not good. One might reasonably suppose that a study of such forecasting failures, if certain abnormalities of the meteorological regime were found to be a recurrent cause of failure, would give an indication of one or more additional variables that should have been included in the formula, but this enticing line of inquiry was apparently not followed up.

Extra Reflexions of X-Rays from Diamond

NEW experimental facts about the reflexions of X-rays by diamond have recently been published with reproductions of the X-ray photographs by Kathleen Lonsdale (*Proc. Roy. Soc.*, A, 179, p. 315; 1942). Two kinds of extra reflexions can be seen on well-exposed Laue photographs. All diamonds show *primary* diffuse reflexions, which are temperature-sensitive but not structure-sensitive. Type I diamonds, only, show *secondary* reflexions (sharp spots, streaks and groups of spots which are not at all typical of diffuse spots in general). They are no more than slightly, if at all, temperature-sensitive and are strongly structure-sensitive. *Primary* and *secondary* reflexions have been observed for many diamonds and in various orientations, associated with the {111} {220} {113} {331} Laue reflexions, using filtered and unfiltered radiation from copper and iron targets. No adequate explanation is yet available of the *secondary* reflexions, taking into account their structure-sensitiveness, the presence of {220} spots and the apparent incompleteness of the groups of spots actually observed.

Space-Charge and Electron Beams

AN informative article by D. P. R. Petrie (*Electrical Communication*, 20, No. 2; 1941) on the effect of space-charge on the potential and electron paths of electron beams presents the more important results of analyses of space-charge in electron streams collected from existing literature, giving them in the form of curves and nomograms suitable for ready application in practice. The effects considered are the space-charge limited current in plane and cylindrical diodes; the minimum potential; maximum current and increase of transit time in the screen - anode region of tetrodes; and the minimum potential, maximum current, velocity distribution and divergence of a long, flat beam between parallel plates and of a long, cylindrical beam in a tube. When an electron stream passes through an electrode system, the potential at any point is lower than that due to the electrodes themselves in the absence of current owing to the surrounding space-charge. In practice, this depression of potential has three important effects: (*a*) the potential may drop to zero at some point, forming a virtual cathode, some electrons being brought to rest there and returning to the nearest positive electrode; (*b*) a beam which would be homogeneous in velocity is rendered inhomogeneous because the potential is depressed by different amounts in different parts of the beam; (*c*) electric fields may be introduced altering the electron paths; for example, an otherwise parallel beam is caused to diverge by its own space-charge. It is important for design purposes to be able to calculate the magnitudes of these effects due to a given current in a given electrode system, but this is possible only in a few cases of simple geometry. Examples are given to indicate the usefulness of such calculations. The possibility of bringing all the indicated results within the scope of a single paper is simplified by the universal appearance in the analyses of a certain fundamental dimensionless parameter which is defined in terms of a current density, a length, a potential, and the ratio of charge to mass of an electron. For completeness, the case of the space-charge limited diode has been included, this being the simplest system the action of which is governed by space charge.

Profiles of Hydrogen Lines in Two Class B Stars

A. Vibert Douglas and D. C. West have compared the theoretical line widths computed by Verweij with profiles of certain Balmer lines in spectra of γ Pegasi and ι Herculis (*Mon. Not. Roy. Astro. Soc.*, 102, 1; 1942). The observational data display marked contradictions, and these show how great are the uncertainties introduced by the method of calibration of a spectrum and the construction of the intensity profile from the microphotometer trace. The material forming the basis of the paper comprises seven 3-prism spectrograms of γ Pegasi and one 1-prism and four 3-prism spectrograms of ι Herculis. From these, microphotometer traces were made and intensity profiles were constructed from the wedge calibration on each plate by means of the reduction data of C. S. Beals (*Pub. Dom. Astrophys. Observ.*, Victoria, B.C. (vi), 9, 98–101; 1934). The actual profiles and also the theoretical profiles of Verweij are plotted and many interesting comparisons are made, very marked discrepancies occurring in some cases. Comparison is also made regarding total absorption in five Balmer lines, and the temperature corresponding to the values of total absorption for $H\beta$, $H\gamma$, $H\delta$ is from 19,000° to 21,000°, though it should be pointed out that these figures were obtained by "making a risky extrapolation". The percentage absorption at line centre is shown in a table and compared with the values obtained by C. T. Elvey and E. G. Williams. An editorial note points out that the hydrogen profiles predicted by Verweij's theory, with which the observations of the paper are compared, are based on Pannekoek's calculated values of the continuous absorption coefficient *k* (*Pub. Ast. Inst. Amsterdam*, No. 4; 1935). Pannekoek has revised these values since, the revised figures appearing in an addendum to the paper referred to.

FORESTS OF NEW ZEALAND

IN the opening pages of the annual report of the New Zealand State Forest Service for the year ending March 31, 1941, by Mr. Alex. R. Entrican, director of forestry (Govt. Printer, Wellington; 1941), presented to both Houses of the General Assembly, a résumé is given of a broad-based and wide-visioned forest policy. The aims laid down are the more significant in that they are expressed with a full knowledge of the calls which the War is making on the forests and the forest service of the Dominion.

On the subject of forest policy, which demands the widest foresight in modern warfare, it is stated that the State Forest Service is rapidly attaining a full war-time footing. As never before, war has reduced all forest issues to one simple problem, that of meeting an increasing and ever-changing demand for timber. Month by month this has claimed more and more of officers' time until in some instances their peace-time activities have been reduced to vanishing point. To conserve man-power, continuation of this trend is inevitable, and the Department's programme of work is being re-oriented accordingly. Fire protection, timber appraisal and utilization activities with their direct contribution to essential war-time production have been intensified, but with two exceptions all other activities either have been or are in course of being reduced to a mere skeleton basis. The two exceptions are staff training and planning, upon which the whole resources of the Department surplus to the war effort must be concentrated.

Prior to the appointment last year of additional technically trained personnel and their assignment to sylvicultural and forest-management duties, it was realized that more particularly in the State exotic forests some losses must be anticipated due to haphazard planning and lack of trained staff over a long period of years. Even prior to the great depression, organization and personnel were entirely inadequate to the Department's rapidly increasing responsibilities, and both the depression and post-depression periods have served to accentuate the disparity between volume of essential work and available trained staff. The seriousness of the position can no longer be ignored, and any attempt to correct it merely by intensification of current training methods must fall far short of minimum requirements. Although military service precludes the training of an adequate junior staff at present, such temporary arrangements as have proved possible have been made, including the establishment of a forest ranger school. It is hoped that at the end of hostilities a number of scholarships in overseas universities will enable forest officers now on military service to qualify for professional duties.

Perhaps the three major forestry preoccupations of the present time are connected with the indigenous forests, the artificially formed exotic forests and erosion. The general forest inventory carried out during 1921–25 demonstrated the necessity for establishing a capital forest resource of exotic softwoods to supplement declining supplies of native timbers until such time as the indigenous forests, which in the past had had to bear the lumbering operations connected with the opening out of lands for farming purposes accompanied by wasteful fellings and fires, could be brought into full productivity. The vital present necessity is the organization of immediate future supplies for the industry not s much for the war period as for its aftermath, whe demand, it is expected, will expand on a considerabl scale. A five-year programme of forest developmen for both Kauri and white pine has been prepare and a survey of standing rimu supplies is in progres It is suggested in connexion with the indigenou forests that consideration will have to be given t the control of fellings on privately owned fores land with the view of conserving supplies and keepin the land reasonably productive, not ignoring th cogent objective of maintaining an effective vegetative cover in the interests of counter-erosion.

On the subject of the private and State exoti forests the report is illuminating. A grave warnin on their poor condition was given in the previou year's report. While interim experience has serve to confirm the worst fears in respect of faults c establishment due to the excessive annual area afforested on inadequate knowledge of localit factors, etc.—wide espacement, choice of wron species and sites, general location, etc.—the indications are that no less trouble is likely to arise throug long-continued neglect of sylvicultural operations Both threaten the health and vigour of many stands some of which may be affected to such an extent a to become potential focal points for widesprea insect and fungal attacks of an epidemic character and others in such a manner as to preclude bot cheap logging and cheap and quick re-establishmen by natural regeneration, thus necessitating slower more costly and less effective re-establishment b planting. As the Director correctly states, thoug the financial authorities in many parts of the Britis Empire have proved hard to convince, "in th ultimate analysis, sylvicultural treatment is no les essential to the continued functioning of the forest than the regular supply of oil and grease to hydro-electric turbines". But this is impossible unles provision is made in the forest budget irrespectiv of whether the operations concerned will be remunerative or otherwise.

The question of soil erosion has been a subject c considerable public discussion; and it is admitted t constitute a serious threat to the success both of th general forest policy and to the future developmen of the saw-milling and allied forest industries. Arden conservationists of the extreme type go so far as t claim that the more inaccessible forests still existin should be reserved from milling operations. "Th Forest Service", says the Director, "continues t advocate a realistic approach to the problem of soi erosion through Dominion-wide control of land burning operations. No other measure can giv such effective results either as quickly or as economically. A conservative estimate of its effectiveness i placed at 80 per cent of the theoretical maximum So aggressive is the New Zealand vegetation that n ground is too barren to resist its invasion—that i if burning is controlled. Too often observation c erosion is limited to pastured slopes heavily scarre or even deeply gullied without realizing that ever forest-clad hillside bears scars and gullies, thoug many are so healed by the ever-invading vegetatio as to defy casual detection. But whereas repeate and uncontrolled burning aggravates and perpetuate the one, controlled use of fire arrests and heals th other. Even much of the harmful effect attributabl to overgrazing is a direct result of indiscriminat burning, and would therefore be corrected by contro of firing operations. Simple as the premise is, i provides the most practicable and economic method of preventing accelerated erosion".

There are many parts of the British Empire where erosion in one form or another is becoming an ever-increasing danger to the means of livelihood of the populations, as is the case, for example, in large parts of Africa. The above remarks of the Director on a suggested method of control may be commended to the administrations concerned; in fact, the whole report—a war-time report—would repay a careful study by all having administrative responsibilities in connexion with the land and its well-being throughout the Empire.

MODERN DEVICES CONTROLLING ELECTRICAL CIRCUITS

A PROGRESS review on "Circuit-controlling Devices on Power Supply Systems" has been given by C. W. Marshall (*J. Inst. Elect. Eng.*, 89, Pt. 1; April, 1942). The review commences with a summary of the technical aspects of power circuit control, considered in three main sections: limitation of current amplitude, limitation of voltage, and making and breaking of circuits.

The paper then proceeds to illustrate what has actually been accomplished by reference to outstanding features of switchgear construction. Illustrated examples are given of a 0·4-kv., 600-amp. air circuit-breaker, a 0·4-kv., three-phase, 800-amp. rating, switchboard, an 11-kv., 750 Mva. metal-clad circuit-breaker, a five-panel assembly of 11-kv., 500 Mva., metal-clad switchgear with circuit-breakers of the draw-down type; the latter are fitted with arc-control devices. A pictorial sectional view of a modern switching unit is given, and shows *inter alia* the circuit-breaker, the means of connecting it to the busbars and to the outgoing circuit, and also the disposition of the current and voltage transformers.

A 33-kv. metal-clad switchgear is depicted, the busbar chambers in this case being filled with 'Freon' gas, and fitted with removable circuit-breakers. A third type of 33-kv. metal-clad switchgear is shown in which small oil-content type circuit-breakers are arranged horizontally. Two other small oil-content breakers are illustrated, one being an electrically operated type with a horizontal breaker, while the other has a vertically mounted breaker operated by compressed air. The last example of 33-kv. practice shows one of the most advanced and interesting designs which is available for commercial application. The general busbar structure follows standard metal-clad practice. The circuit-breaker, however, is of the air-blast type and this development is believed to be unique.

Two examples of 66-kv. switchgear are shown, the first being of the vertical type with double busbars and oil-immersed busbar selectors, while the second is a single-break, small-oil-volume, porcelain-clad unit. A group of 132-kv. units is shown, including a large-oil-volume circuit-breaker originally fitted with four open breaks and converted to a double-break type with arc control. Another illustrates the transition from the large-oil-volume circuit-breaker with steel tanks to the small-oil-volume, porcelain-clad type. A cross-sectional view illustrates all the essential parts of one phase of the breaker, and a photograph shows the complete assembly of a three-phase unit and offers a good idea of its size.

The practical performance of the various classes of installation is assessed, short-circuit test performance figures are given for typical circuit-breakers, mention is made of the test performance of modern fuses, and a tribute is paid to the remarkable efficiency of the various short-circuit testing stations. The period reviewed has been remarkable for the advance in knowledge of the intimate phenomena of arc rupture due to the fundamental research work of the British Electrical and Allied Industries Research Association, supplemented by the development work done in the various British switchgear testing stations.

A.R.P. AND THE ENGINEERING INDUSTRY

A CONFERENCE on air-raid precautions and the engineering industry arranged by the Institutions of Electrical, Civil and Mechanical Engineers with the co-operation of the Ministry of Home Security (Research and Experiments Department) was held at the Central Hall, Westminster, on December 9, and summaries of the three addresses delivered are contained in the *Journal of the Institution of Electrical Engineers* (89, Pt. I, April, 1942).

In an address on the "Effect of High Explosives on Structures", Prof. J. D. Bernal said that the main effects of explosions were covered by describing the arrival of the bomb or mine, and then the three chief mechanisms by which mines and bombs cause damage: blast; bomb fragments; earth shock when a bomb explodes in the ground. The distance a bomb travels before exploding is of more importance than the distance of penetration. This is determined not by the penetrating power but by the kind of fuse it carries. The distribution of fragments from a bomb exploding in air was explained to consist of three zones: those shot off at right angles to the side of the bomb, forming the main fragment zone; tail fragments, usually light; and nose fragments, usually heavy. The simple physics of the released gases was explained in connexion with peak blast pressure. An analysis was given of the reactions of a structure to blast, mention being made of the fact that resonance can be a contributory cause to damage if the half-period of the structure is of the same order as the time-interval between maximum pressure and maximum suction. The effects of shock waves from bombs exploding subterraneously were also described.

Prof. J. F. Baker dealt with the "Design of Protective Structures and the Defence of Industry" in an address which described principles of structural design for protecting industry from air attack which, though unfamiliar in normal engineering practice, can claim recognition as rational. Effective resistance was explained to be achieved by resistance accompanied by provision against failure by shear, while ductility in material and continuity in structural form combined with mass are essential if the structure takes the form of a wall. Recommendations were made for the protection of workers by shelters, and suggestions made as to a rationalized system of structural design for strengthening floors to carry loading by debris and for stability under earth shock. The criterion of proper protection was stated to be such that, having regard to war hazards, the total probable output over a period of all existing factories shall be thereby increased by a greater amount than if the work had gone into building new factories to be equipped with machine tools, the economic standard of protection depending ultimately on the scale of air attack.

A survey was made by J. W. Martin of the "Gas Contamination Problem in the Engineering Industry, with Special Reference to Electrical Machinery", and it dealt with the effects of gas contamination on the properties of materials and the functioning of machines, and with the consequent risk to workers operating the machines, or working near enough to be affected by vapour. Particular problems arise in connexion with the insulation of electrical machinery. An important factor in electrical work is the specific resistivity of liquid gases, owing to the danger of flashovers. It was concluded that the chances of contamination causing serious dislocation of industry are not high, and risks can be appreciably reduced by relatively simple means. Where contamination of plant occurs it need not mean the closing of works for long periods. It is advisable to replace the intricate and complicated instruments and components of plant that become contaminated. The emphasis should be on putting the plant into operation, contaminated work in progress being dealt with as a salvage operation.

FORTHCOMING EVENTS

(Meeting marked with an asterisk is open to the public)

Tuesday, June 16

Royal Anthropological Institute (at 21 Bedford Square, London, W.C.1), at 1.30 p.m.—Dr. Alf. Sommerfelt: "The Social Origin of Linguistic Categories".

Wednesday, June 17

Institute of Chemistry (London and South Eastern Counties Section) (in the Chemistry Lecture Theatre, West Ham Municipal College, Romford Road, London, E.15), at 6 p.m.—Dr. H. Baines: "Recent Advances in Photographic Theory".

Thursday, June 18

Chadwick Public Lecture (at the Chelsea Physic Garden, Swan Walk, London, S.W.3), at 4 p.m.—Mr. E. Augustus Bowles: "Plants in relation to Food, Medicine or Poison".*

Chemical Society, Institute of Chemistry and Society of Chemical Industry (Bristol and South-Western Counties Sections) (in the University Chemical Department, Woodland Road, Bristol), at 6.30 p.m.—Mr. J. Lumsden: "Statistical Methods Applied to Chemical Problems".

Saturday, June 20

Institute of Physics (London and Home Counties Branch) (at the South-West Essex Technical College, Forest Road, Walthamstow, London, E.17), at 2.30 p.m.—Conference on "The Eye in Industry".

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Lecturer (Woman) for Geography and Mathematics in the Crewe County Training College—The Director of Education, County Education Offices, City Road, Chester (June 18).

Lac Information Officer—The Central Register (Reference O.N.F. 547), Ministry of Labour and National Service, Sardinia Street, London, W.C.2 (June 20).

Chief Lecturer in Mechanical Engineering—The Principal, Walsall Technical College, Bradford Place, Walsall (June 20.)

THE FUNCTION OF BRITISH RESTAURANTS

BRITISH Restaurants may be said to have started as an improvisation and to continue as a compromise; how they will develop in the near and distant future is uncertain. Their original object was to supply a solid meal to those who, owing to bombing, could not get their meals in their customary way; but other objects have been grafted on. First, they serve the same purpose as works canteens, they supply meals to workers in factories that are not covered by the Factory Canteens Order, and to others who work far from home. Then there is the economy motive; they reduce waste of foodstuffs; less labour is needed for preparing and cooking food when a hundred or more are fed in a restaurant than when they eat in groups of three and four at home. Women are better able to go to work in factories if they are relieved of the task of preparing the main meal of the day. Finally, there is the motive that has been behind the expansion of the school meals service—improvement of the standard of nutrition; the British Restaurants insure that anyone can get a nutritious meal at a low price.

As the knowledge that meals in British Restaurants are good and cheap has spread, more and more people have gone to them; so that now, besides factory and clerical workers and shop assistants, professional men and women, students, bishops and tramps now eat together in a friendly and sociable atmosphere. All of which is excellent; but the time has come to think about the consequences and the whole purpose of these communal meals. As it is, they encroach on the business of private caterers; they threaten to disturb the business of food retailers; and if they come to serve a large proportion of the population they will upset the system of rationing, particularly of meat. In January of this year Lord Woolton assured a deputation from various caterers' associations that if a local authority wished to open a British Restaurant and the local caterers think it unnecessary, an official will be sent to investigate before approval is given by the Ministry. This may mean much or little; all depends on the criteria on which the Ministry's decision is based. Some day it will be necessary to decide who it is that the British Restaurants are intended to serve, and what purpose they are intended to play in our system of food control. It may be assumed that they are intended to provide for those workers who cannot go home for their midday meal. It might seem desirable to carry the system to its extreme and to supply the whole population with a solid meal in a British Restaurant. As we shall see later, it is doubtful how far this could be justified, even on the grounds of economy; but in any event expansion is limited by other factors.

The present British Restaurants, particularly the older ones in London, must be improved if they are to continue to supply satisfactory meals under favourable conditions. The shortage of equipment is being overcome; small tables with green linoleum tops are taking the place of trestle tables, and chairs are supplied in place of benches. The newer restaurants are so arranged that customers pass a series of hatches from which they can take their food; but in the older restaurants they wander from one serving table to another. The worst trouble is overcrowding; customers who come, and must come, at the rush times have to wait in long queues; in the dining-rooms there is no space between the backs of the diners' adjoining tables. Partly because of the time wasted in the queue, partly from a feeling that they must finish and make room for others, diners hurry over their meals. This overcrowding results, in the main, from the need to improvise restaurants in any buildings available, however unsuitable or small. One may contrast the British Restaurant in Dunmow, in which the kitchen is on an upper floor, and the dining-room (the sorting room of the old Post Office, with a glass roof) is bright and airy, with one near Red Lion Square, London, in which the food is cooked and eaten in the same overcrowded room. No other building can be found in the neighbourhood; most that might have served have been destroyed by bombing. As no extensive building is allowed at present it will be difficult to relieve this overcrowding unless some private premises are commandeered. Even with more and better buildings it may not be possible to staff them. As more women are drawn into the Services or into industry it becomes more and more difficult to find both paid cooks and voluntary helpers. It is, therefore, hard enough to cope with the present number of diners; and, as the demand increases, it will be necessary to select the patrons in some way if no further provision is made for the meals service.

Agreeing that one of the purposes of the British Restaurants is to raise the level of nutrition, how far can they be used as media for education in the better use of food, and how far can they be improved? At present most of the meals consist of the traditional meat and two vegetables, followed by pudding. It is suggested, for example, that meals of the Oslo type might be introduced. However, this education needs a personal approach. If the diners are merely supplied with strange food they may eat it, but they will not come again. The personal approach is possible in schools and in some factory canteens; but it is out of the question when diners enter in a queue of a hundred or more, and eat hurriedly in a crowded room; certainly none of the staff has time for discussion during meal times. A nucleus of diners ready to set an example by eating different food may influence the rest; but with a small staff and large numbers to serve, it is not possible to prepare the special dishes needed.

Critics of the meals provided should realize that there is much sound physiology behind the traditional dinners. The meals have been stigmatized as 'too starchy'. But starch is the main source of energy of the people of the world. A few only of the more favoured; whose energy expenditure was not large, may have been able to get a fair proportion of their daily calories from protein and fat; but in the present days of shortage this is not possible. The rations even to canteens for heavy workers, allow only some 200 mega-calories per meal from meat, cheese and butter. If the meals supply, as is intended, about one third of the day's energy requirement, the greater part must be derived from starchy foods. Actually Miss Abrahams reported to the Nutrition Society's Conference on May 30 (see p. 685 of this issue) that only a few of the meals that she measured supplied 1,000 mega-calories—one third of the 3,000 mega-calories that are commonly accepted as an average day's requirements. It would be better if the starchy food, bread, were supplied free in all restaurants, in order to ensure that sufficient energy should be furnished by the dinner. Also critics should be sure that their criticisms are sound. Most manageresses have been told that a large proportion of vitamin C dissolves out of potatoes if they are peeled and left in water overnight; that they should, therefore, be peeled in the morning before cooking. Anyone who has had practical experience of the difficulty of the extraction of ascorbic acid from raw potatoes, even when they are ground up, would suspect the first statement; actually experiments have shown that it is untrue. No methods by which the staff could peel some hundredweights of potatoes in the morning in time to be cooked were ever suggested. Because of the practical difficulties involved in its application this particular piece of advice has been remembered when better things have been forgotten, and most manageresses are left with the belief, however politely concealed, that dietitians are armchair faddists. Similarly, it is not possible, with limited equipment and with limited time, to put green vegetables into the boiling water in small instalments. However, as the experiences related at the Conference showed, the preparation of vegetables in some kitchens is unsatisfactory, and improvements, with the object of conserving vitamin C, are possible.

Two methods whereby the meals might be improved may be suggested. First, arrangements might be made for visits by manageresses to restaurants in other districts, so that they might exchange experiences. A conference of restaurant staffs might help; it is a matter for regret that only one speaker at the Conference of the Nutrition Society put the view of a manageress. Second, an experimental team might visit those restaurants in which there is room and demonstrate new methods of using food; this would certainly be possible with the Oslo type of meal. In the meantime, studies on the nutritional value of the meals, as served, should continue.

There are two possible changes that do not directly concern the staff of the restaurant. First, the working-class adolescent is, as usual, forgotten. He or she needs extra protein just as much as a school-child. True, he *may* get 1½ pints more milk per week than an adult, but this supplies only 4 gm. of protein per day; and, as an adolescent is not (and if female, never will be) regarded as a 'working man'; he (and still more she) is not likely to get his or her full share of the family meat ration. There is a good case for doubling the meat allowance for all who are under the age of eighteen, as shown by their identity cards. Also it should be possible to make a reduction in cost for the under-eighteens; otherwise the meals will take up too large a fraction of what is left of their wages, after unavoidable expenses are met. Actually, in many restaurants the proportion of the diners who are under eighteen is very small, possibly because they find the cost too high.

Another change that should improve the quality of the meals is an alteration in the system of buying. The principle has been to use the normal channels of trade. Most British Restaurants get their supplies of meat, fish, dairy products and vegetables from local retailers at full retail prices, or less a small discount only. The system of central buying should reduce the cost and, particularly with regard to vegetables, improve the supply. The risk of deficiency of vitamin C during the early months of the year, now that imported fruit is almost unobtainable, was discussed at the Conference. Attention was focused on the conservation of the vitamin C of vegetables, either by better cooking or by no cooking at all. No mention was made of another aspect of the food situation; vitamin A from animal sources (milk, butter, margarine, cheese and eggs) is limited by rationing by an average of some 1,000 international units per day; the rest of the requirements must be made up from the carotene of roots and, particularly, of green vegetables. The supply of carotene falls off in March, just as much as that of vitamin C. True, stores of vitamin A can be accumulated in the body when the intake is high, but there is little likelihood of a liberal supply of vitamin A at any time of the year. The situation with regard to vitamin A would not be affected by changes in methods of cooking; but an ample supply of green vegetables would satisfy requirements of both vitamin C and vitamin A.

At present the vegetables grown on a large scale are mainly those that travel well, for example, cauliflowers and the compact type of cabbage with a white heart; both of these contain relatively little carotene. Winter hardy greens, such as curly kale, and sprouting broccoli, that comes early in spring, are neglected. There is a contrast between country schools that grow their own vegetables, and country British Restaurants that buy from a shop; and between British Restaurants in town and those in the country, since the best supplies go straight to town. One British Restaurant in a small town had a difficulty in getting green vegetables during the second week in May of this year. The difficulties of provincial British Restaurants could be overcome if local authorities grew their own vegetables or contracted directly with local growers, and arranged what should be grown. Some such local organization would do much to prevent the waste and expense of the distribution of vegetables that were exposed in the debate in the House of Lords on June 3. But if the experience of this year, when for three weeks in March little green stuff except brussels sprouts at 10*d*. or more per lb. could be bought, is to be avoided next year, something must be done at once.

Another improvement which a central organization of the food supply would make possible is the introduction of central factory kitchens as described by Mr. Le Gros Clark at the Conference. This would relieve the staffs of restaurants of a considerable fraction of the work of preparing food and allow a greater variety of dishes at any restaurant.

If British Restaurants are continued after the War ends, they may cater for a small proportion of the population, as at present, or they may be extended until they replace the family system. It cannot be assumed that such an extension is justified on grounds of economy alone. At first sight it seems obvious that fuel is saved and labour better used if many small cooking units are replaced by one large unit. But actually domestic economy is an integrated whole. If one part is taken away the system works less economically. The kitchen fire not only cooks the dinner but also heats the house, besides water and other meals. If it is not used to cook dinner its use for other purposes becomes wasteful. In the same way the housewife spends her time in many other household jobs besides cooking dinner, and she may have to look after children. If the labour of a mother with young children is used outside her home, someone else must at least look after her children while she is away. This means crèches or nursery schools, premises to accommodate them and qualified women to look after the children. Even then there remain jobs to be done before and after working-hours—washing children and attending to clothes, cleaning the house, and getting other meals. If a woman does this as well as an ordinary day's work, it is not an economy of labour, but sweated labour. A general system of communal meals, with employment of married women outside their homes, can be justified on grounds of economy of labour only as part of a complete system of communal life, with homes reduced to dormitories rather than living places.

In the U.S.S.R. communal meals have been encouraged for much the same reasons as have led to the introduction of British Restaurants; there was also the factor that they fitted the Bolshevik outlook; they, together with the type of housing adopted, were part of a communal system. However, Le Gros Clark and Brinton in 1935 found a tendency to revert to eating at home. It would be interesting to know how the matter stood in 1939. Communal restaurants were started in Germany and Austria in the large towns during the War of 1914–18, and remained open after the War. In Vienna they were still running up to the time of the *Anschluss.* They were mainly found in the central part of the city and fed a larger number than do the British Restaurants in the central parts of London. They catered mainly for the working population of the city centre (which included few factory workers) and people who preferred to eat away from home. A good three-course meal with a choice of dishes cost one schilling (equivalent to about 10*d*.); a large *eintopf* dish was still cheaper. It was not possible to prepare similar meals so cheaply at home.

This is the type of service that the British Restaurants will, in all probability, offer after the War. As building becomes possible better premises should be provided and various meals at different prices be introduced. We may hope that in the end the

Restaurants will not only insure a good level of nutrition by supplying good meals at low prices, but will also provide amusement and entertainment, much as in J. B. Priestley's vision of "Smoketown". Whether they come to form part of a complete system of communal life it remains for the future to decide*.

---

* For a general account of British Restaurants, Works and School Canteens see "Community Feeding in Wartime" by Barbara Drake (Fabian Society) and, for organization, a pamphlet with the same title published by H.M. Stationery Office.

LIFE AND LABOUR

Fighting for What?

By Sir John Orr. Pp. xiv+90. (London: Macmillan and Co., Ltd., 1942.) 2*s*. 6*d*. net.

"A THIRD of the population in the United Kingdom and about an equal proportion in the United States do not enjoy food and shelter on the standard needed for health. In most other countries, the proportion of the population which has never been adequately fed or adequately housed is even higher. Among the native races, for whose welfare Britain is responsible, only a relatively small proportion of the population have houses in which they can live in decency and food on the health standard."

These are Sir John Orr's words; and they are an indictment by science against society preferred to a world jury at a critical epoch in the history of civilization. As the result of many investigations carried out in recent years at a number of scientific institutions, the minimum and optimum nutritional needs of human beings have been determined, and general agreement has been reached as to dietary standards necessary to maintain health and growth. When the constituents of a diet are wrongly balanced, as measured by these standards, or when the supply of foodstuffs is inadequate, there is an increase in the incidence of deficiency diseases and a weakening of resistance to others, as well as stunted growth and general physical disability. Over-feeding, like other forms of intemperance, brings its own penalties upon the body and mind, and is a type of malnutrition due to self-indulgence rather than to lack of knowledge of dietary requirements.

Dietary habits can be improved by increasing the interest of public health authorities in the modern science of human nutrition and its everyday applications. No educational agencies of this kind can, however, be of much value unless the foodstuffs required for dietary standards are within the reach of all who need them. To advise people what they should eat to maintain health and strength, and not to ensure that they can obtain the food they require, is to make a mockery of knowledge. It is comparable to the naïve suggestion related in French history that if a starving people could not obtain bread they should eat cake. The position to-day is that there is close agreement between scientific investigators and official bodies as to standard food requirements of human beings. It has also been established that, with the approach of diets to this standard, health and physical fitness are improved and the further the diets fall below the standard the worse these bodily conditions become.

An apocryphal story relates that after Galileo had shown to Pope Urban VIII that the earth revolved around the sun and not the sun around the earth, the Pope replied: "That is all very well, Galileo, but what are you going to do about it?" Similarly, as science has shown clearly what are the primary nutritional needs of man and also enabled them to be supplied in increasing abundance from the earth's store, social justice demands that something should be done to ensure that no member of the community is deprived of the means of healthy living. It may be trite to deplore the prevalence of poverty in the midst of plenty, but dietary poverty is preventable and ought, therefore, to be prevented, if only to save the social arteries from sclerosis.

In order to bring the diet of the whole population up to the health-level defined by the accepted standards of nutrition, additional amounts of protective and other foods would have to be made available for consumption. Whatever is required to reach this standard can be produced, and there cannot be over-production of foodstuffs so long as any human beings are hungry for them. It is possible to estimate with reasonable accuracy the food requirements of any community and to produce whatever is needed for the healthy nourishment of all members of it. To ensure these conditions demands, however, the institution of a food policy based on human needs and not dependent upon the profit-making interests of producers or distributors. Until these needs are satisfied, the problem of over-production cannot arise, and the wanton destruction of foodstuffs will be condemned as a crime against the community.

When the principle is conceded that the whole population should be able to obtain sufficient food to reach at least the minimum dietary standard, various difficulties arise in applying it. In pre-war days Great Britain imported about two thirds of the food she consumed. Both home production and imports would have to be increased in order to supply the necessary food on a free-choice basis. Sir John Orr contemplates a great expansion of agriculture at home and abroad to provide such supplies and suggests what foods should be produced in Great Britain and what should be imported in order to raise the total supplies to the level of consumption required for a health basis. This means a re-orientation of British agricultural practice towards that of Denmark and Holland, to supply foods which can be produced at home as easily and cheaply as they can be produced abroad, and the importation of such foods as wheat, beef, mutton and sugar which cannot be produced as economically here as in some other countries. There must be a great expansion of agriculture at home in order to produce the additional amounts of food required for home consumption, and the increased imports of food and feeding-stuffs would require increased exports of industrial products to pay for them. Increased agricultural and industrial output means increased employment and the creation of new national wealth as well as stability in trade.

The foodstuffs necessary to bring all the members of a community up to the safety-line of health are known just as a farmer knows what he has to produce or purchase to feed or fatten his herds of cattle. We know also that the amounts required can be produced and ought to be made available to the whole population. The principles of Sir John Orr's food policy are based upon these scientific facts. Their recognition makes supply and demand matters of international concern instead of profit and loss accounts of small or big businesses. With agriculture based on the needs of the population and industry expanding with it, production and trade would tend to become stabilized and the booms and slumps of food markets would be avoided.

A food policy based on the needs of the community and not upon considerations of private profit by business people who control the food industry would eliminate many vested interests and meet, therefore, with much opposition. When, however, the social conscience is convinced that the principles and the aims are right, action is bound to be taken to carry them out. Sir John urges that we should not wait until after the War to produce plans to enable this to be done. He suggests that a Food Planning Commission should be established now, and outlines an organization which might be devised for Great Britain. A National Food Board should be appointed by the Government and the members of it should be financially independent of the food trade. The National Board would be responsible for bringing the national supplies of the main foodstuffs up to the level needed to supply sufficient for everybody and for arranging that sufficient would be available within the purchasing power of everybody. The Board would exercise its functions through a number of Commodity Boards the members of which could include representatives of producers, distributors, consumers, and taxpayers, as well as of people having no financial interests in the food trade. These Commodity Boards would take over the functions of the existing Agricultural Marketing Boards, but would differ from them in not having the power to regulate production and fix prices in their own interests.

When the aim is to enable the whole community to obtain the food required to live, no sectional interests or actions should be tolerated which will prevent its attainment. The new policy involves certain changes in the food trades, but there is no reason why these should deprive producers and distributors from exercising initiative and free business enterprise for services supplementary to those of the Commodity Boards. Scientific inquiries have shown what a dietary standard for human beings signifies, both as to needs and increase of production necessary to satisfy them. There will have to be new economic policies and new international relationships if the necessities of life on a health standard are to be brought within the reach of all mankind. These elements of a new world constitution must be organized by financiers and traders not for their benefit alone but also as worthy service to the community.

Each country has its own problems of this kind to solve in order to bring an adequate diet within the purchasing power of the people in it, and in a world food policy every nation has a similar human responsibility towards poorer nations. This is already recognized in the steps being taken to provide food for peoples who have been deprived of it by conditions of war, and in the preparation of plans for post-war production and supply. Modern contributions to the science of nutrition, and the inquiries into the social economics of rich as well as of poor countries, have shown that a food policy such as that long advocated by Sir John Orr and outlined in the present book should be adopted by the United Nations as the sound and sure foundation of world stability. There are still many people who regard such an outlook as Utopian and unattainable, but the signs of the times are against them. The principles of the Atlantic Charter represent relationships which might well become articles of social faith among all free peoples and inspire a crusade to promote their application.

Since these principles of the cause for which the United States and the United Kingdom are fighting were stated, there has been a tendency to believe that action based upon them would not come above the horizon until after the War, and possibly not then. The announcement made by Mr. Roosevelt and Mr. Churchill on June 10 should remove all doubt as to their joint intention to put into practice the policies expressed in their Charter. In order to promote the most effective use of the combined resources of the United States and the United Kingdom for the prosecution of the War, they have established a Combined Production and Resources Board and a Combined Food Board. The purpose of the Food Board is to co-ordinate and obtain a planned and expeditious utilization of the food resources of the United Nations. All questions of supply, production, distribution and disposal of foods in which the Governments of the United States and the United Kingdom have common concern will be referred to the Board for inquiry and report, and also those relating to agricultural materials from which foods are derived and equipment and non-food materials used in the production of such foods. Moreover, the Board is to work in collaboration with others of the United Nations towards the best utilization of their food resources, and with any interested nation or nations to formulate plans and recommendations for development, expansion, purchase or other effective use of their food resources. The functions of the Board thus follow much the same lines as those of the organization outlined by Sir John Orr. The establishment of the Board gives good reason to expect the realization of his hope that "the Government is prepared to base post-war food policy on human needs and to co-operate with all other Governments to apply such a policy on a world-wide scale".

The two other primary material necessities of life are adequate housing and the opportunity to work. When the provision of the additional food and decent homes for all members of the community is undertaken by public authorities, and every citizen, rich or poor, is made to serve for a period in a National Service Corps, the unemployment problem will approach solution, and for the first time in history man will attain economic freedom. This is the cause for which Sir John Orr and many other social reformers are combining scientific knowledge with prophetic vision. It appeals to men of all creeds in all lands and makes world fellowship possible on a basis of common social needs and faith in the capacity of Nature and the spirit of humanity to remove the fear of want from the lives of all the peoples of the world. It was said long ago that "the poor shall never cease out of the land; therefore I command thee, saying, Thou shalt open thine hand wide unto thy brother, to thy poor and to thy needy in thy land." The "land" of Deuteronomy now extends to the whole earth and "to the children of men" dwelling in all parts of it. Every human being has a right to a just share of the fullness thereof and the obligation to add to his inheritance. Though the poor may always be with us in families and in nations, they should not have to depend upon alms-giving for the primary necessities of life while Nature and man can produce these in full measure and in the spirit of mutual aid. Sir John Orr's book is a stimulating call to all men and women of goodwill to join in a crusade to achieve this end.

R. A. Gregory.

NEW ATOMS FOR OLD

Mass Spectra and Isotopes
By Dr. F. W. Aston. Second edition. Pp. xii+276+12 plates. (London: Edward Arnold and Co., 1942.) 22*s*. 6*d*. net.

THE atomic theory of Dalton, accepted after many misgivings by nineteenth-century chemists, is now essentially discarded; Prout's hypothesis, rejected by Stas as "nothing but an illusion, a mere speculation definitely contradicted by experience", has returned to favour. One of the main factors in this transformation has been the discovery that the majority of the elements exist in two or more forms, which are chemically identical even though their atomic masses differ. These diverse species of the same element are known as isotopes, and when the word isotopes is mentioned one immediately thinks of Aston.

Although this welcome volume is announced as the second edition of "Mass Spectra and Isotopes", it constitutes in reality the fourth edition of Dr. Aston's pioneer monograph on "Isotopes", first issued in 1922. The change in title made in 1933 did not, as might appear to the casual eye, indicate a broadening of the ground covered. On the contrary, as the author himself specifically pointed out in his preface, the large development of the subject led him then to narrow the scope of the book a little—"it is now concerned less with general theory and more with experimental results, especially with those obtained by mass-spectrum analysis". The present edition very wisely continues this policy of restriction.

No doubt there will be readers who will regret that the book does not contain any discussion of induced radioactivity and artificial isotopes, but if Dr. Aston was justified in allotting a "somewhat disproportionally large space" to inactive isotopes twenty years ago in the hope that the inadequacy of his account of radioactive isotopes might stimulate the production of a separate volume dealing with this field, then it is obvious that it would be an impossible task nowadays to compress even a summary of all the important recent work on synthetic isotopes into a volume describing the stable isotopes in detail. One task at a time is prudent procedure, and Dr. Aston is entitled to feel a considerable amount of satisfaction in the fact that, in one important sense at least, the task to which he has devoted himself almost uninterruptedly for thirty years—the complete tabulation of the stable natural isotopes—has at length been triumphantly concluded. To quote his own words: "All the elements have now been analysed, and my main concern in writing this book is to tell how this has been done".

The tale is a thrilling one, and it is admirably told. The volume is indeed, in a fashion, a detective story of the very first class; Hercule Poirot or Lord Peter Wimsey would envy the skilful way in which one minute clue after another has been first distinguished and then relentlessly followed up until every atom of information has been drained out of it which might lead (and in every case, has led) to the identification of each individual connected with the mystery. No element possessed of a double, or multiple, personality has succeeded in concealing its duplicity, or multiplicity. "*Elementary*, my dear Watson!" might well be the motto on the title-page.

The experimental work involved, bristling with fresh difficulties at each forward step, has been meticulously careful from the very start, and has now attained an almost incredible order of accuracy. A most valuable feature of this edition is the inclusion of an entirely new chapter recording the remarkable recent advances in design of mass spectrographs, particularly the double-focusing types. The increase in exactness obtained by the employment of these formidable instruments may be recognized, in a very simple manner, by a comparison of Aston's original packing fraction curve (p. 81) with Dempster's 1938 model (p. 108). The atomic masses of all the significant natural isotopes of every element and their relative abundance have now been established with such certainty as to warrant the astounding statement (p. 216) that were the vast accumulations of chemical data comprising the grand total of direct atomic weight determinations lost, the table of atomic weights could be reconstructed to-day, entirely from mass spectrum evidence, as complete and, with the possible single exception of the element copper, as accurate as the table we now have.

Especially interesting in this connexion is the history of hydrogen, since it was an infinitesimal disagreement between the chemical and mass-spectrograph atomic weight values for this element that first led Birge and Menzel in 1931 to point out that, to bring the results into accord, hydrogen must contain heavier isotopes. Here the amusing case of a false clue leading to a correct deduction, rare in detective novels but still rarer in scientific work (Prout's hypothesis is an apposite example), is beautifully exemplified. "Fortunately unaware that, as we now know, the error in *each* of the estimates concerned was greater than the *total* discrepancy he was seeking to explain, Urey started his famous painstaking search which resulted in the remarkable discovery of heavy hydrogen, and for which he received the well-merited award of the Nobel Prize in 1934."

The fact that there are still plenty of unsolved problems in the general theory of the subject is well illustrated in Chapter 13, which deals with "Isotope Statistics". A number of interesting rules are cited, but their basis is admittedly still obscure in most instances. For example, why should elements of odd atomic number never have more than two stable isotopes, while elements of even atomic number may have up to nine or ten (p. 204)? Why should elements of even atomic number predominate to a very marked extent not only in the earth's crust, but also in such extra-terrestrial matter as meteorites (p. 207)? And why should there be so little apparent rhyme or reason in the relative abundance of isotopes (p. 210)?

Dr. C. P. Snow has made an excellent revision of the two chapters on the isotope effect in molecular and atomic spectra, which he wrote for the previous edition. In the whole book, I have detected only one error, namely the statement (pp. 259–60) that Lewis and Macdonald's partial separation of the isotopes of lithium was founded upon "the difference in the free migration velocities of ions"; it depended, in fact, upon a difference in their electrode potentials. In return, however, I am prepared to admit that I have corrected quite a number of false impressions in my own mind through the perusal of the volume, and have acquired a veritable mass of new knowledge. I venture to advise all my chemical and physical colleagues to go and do likewise.

JAMES KENDALL.

ECONOMICS IN THE U.S.S.R.

Soviet Economy and the War

By Maurice Dobb. Pp. v+88. (London: George Routledge and Sons, Ltd., 1941.) 3*s*. net.

Dear Joe

Letters from Bill Smith to Joseph Stalin. By E. W. and M. M. Robson. Pp. 96. (London: Martin Secker and Warburg, Ltd., 1942.) 2*s*. 6*d*. net.

THE closer political collaboration between Great Britain and Soviet Russia which has now materialized is as essential to the establishment of order and freedom in Europe when victory has been won as it is to the victory of the United Nations. That collaboration can scarcely be fully effective unless it is based on a mutual understanding and respect, and there is still room for literature which is designed to remove misunderstandings and give something more than a superficial picture of life and thought in the two different societies. Far too much of the mass of literature on Russia in Great Britain is objective, if not undisguisedly biased in one direction or another or frankly propaganda. Mr. Maurice Dobb's "Soviet Economy and the War" is a modest effort at an objective account of the economic system of Soviet Russia with reference to Russia's part in the War, and he stresses the urgent need for a more just appraisal of Soviet economy to-day if the alliance is to bear fruit in a practical policy and lasting co-operation of the two peoples. Mistakes in our foreign policy towards the U.S.S.R. will assuredly be repeated in the absence of accurate and unprejudiced knowledge of the economic and military potential of our ally.

Mr. Dobb makes a definite contribution to that better understanding, and he should at least banish the complacent assumption that the U.S.S.R. can bear the full weight of German war economy. For waging a prolonged war of attrition, he concludes that the U.S.S.R. is weaker than Germany as regards the economic basis of her war effort, if she has to face alone the full onslaught of the German war machine, although in some respects the U.S.S.R. is immeasurably stronger than in the difficult days of the First Five-Year Plan a decade ago. Apart from this, Mr. Dobb gives a clue to the root cause of the very high degree of initiative, as well as of morale and of enthusiasm, which has been shown by the ordinary people in the Red Army or Air Force and as guerilla fighters, or in the factory or ordinary civilian life. The value of the training and organization, under Soviet economy, of the ordinary workers and salaried staffs in industry, to participate in the discussion and concrete criticism of policy before it is made has received striking demonstration.

E. W. and M. M. Robson's book is another attempt at the interpretation of the British order of society with the view of mutual understanding. Written from the British point of view, it is acutely but constructively critical of certain elements of weakness in the Soviet order, and administers a wholesome corrective to some of the fulsome adulation of Soviet ways and ideas which has recently been popular. Unfortunately, much of the book is far from easy reading, and neither the exposition of the ideas or traditions of Anglo-Saxon democracy nor the analysis of those developments in Russia, belonging to the negative side of the revolution, which led to the signature of the pact with Hitler, are by any means so lucid as could be desired. None the less, the glimpse of the possibilities of Anglo-Soviet co-operation, and of renewal of the creative forces in both countries through the positive elements which have inspired such magnificent resistance to aggression, warrants the hope of a further attempt on similar lines with a wider and more popular appeal.

R. Brightman.

GEOLOGICAL TEXT-BOOKS

Lake and Rastall's Text-Book of Geology

Revised by Dr. R. H. Rastall. Fifth edition. Pp. viii+491+32 plates. (London: Edward Arnold and Co., 1941.) 25*s*. net.

Introduction to Geology

By Prof. E. B. Branson and Dr. W. A. Tarr. Second edition. Pp. ix+482. (New York and London: McGraw-Hill Book Co., Inc., 1941.) 26*s*.

Field Geology

By Dr. Frederic H. Lahee. Fourth edition, revised and enlarged. Pp. xxxii+853. (New York and London: McGraw-Hill Book Co. Inc., 1941.) 35*s*.

EVER since its appearance more than thirty years ago, "Lake and Rastall" has been recognized as our leading elementary text-book on geology. Now, in its fifth edition, it has been carefully revised and largely rewritten by Dr. Rastall. While the general plan remains unchanged, the balance of the various topics has been improved and the treatment modernized. Some sections have been shortened or omitted (for example, certain details of mineralogy and petrology) to make room for new matter concerned with subjects in which there has been considerable recent progress, as in the chapter on sedimentary rocks. In revising the stratigraphical chapters, the admirable regional handbooks issued by H.M. Geological Survey have been fully utilized.

Here and there revision has perhaps not gone far enough. Neither the intrusive masses of the Cuillins and Red Hills of Skye (p. 247) nor the granite intrusion of the Cheviots (p. 475) should now be considered as laccoliths. In the classification table on p. 263 there is still no indication that plagioclase is an essential mineral of alkali-gabbro. The old interpretation of the nickel ores of Sudbury as segregations of immiscible sulphides (p. 265) is no longer tenable, since the ores are now known to be of later origin than the basic rocks with which they are associated. In connexion with the emplacement of igneous rocks there is some confusion on p. 264 between melting and overhead stoping, while the use of the term "melting" (pp. 13 and 250) hides the fact that granitization involves a change of chemical composition. However, these are minor defects, mostly inherited from earlier editions.

A particularly laudable feature of the book is the refreshing absence of dogmatism and the frank recognition that many of the hypotheses concerning fundamental problems are still little more than speculative. "Lake and Rastall" has always been esteemed for the broadness of its scope, the clarity of its style and the unfailing interest of its treatment. In this new edition its high reputation should be still further enhanced.

Branson and Tarr's "Introduction", which deals with both physical and historical geology, is now, in its second edition, a far more attractive volume than before. The most conspicuous change is to be found in the illustrations; several new ones have been substituted and all of them are now very much more effectively reproduced. The revision of the text has been confined to bringing the work up to date, simplifying certain sections that were found to present difficulty, and omitting technicalities that are believed to be "beyond the comprehension of elementary students".

In some respects the result is probably too simple for a first-year university course. It is claimed that igneous rocks can be determined by means of a cross classification based on (*a*) colour and mineral composition—light and dark in each case, against (*b*) structure—grained, dense, glassy and fragmental. Fig. 9 brings together all the common modes of occurrence of igneous rocks in a most unnatural and misleading association. Sedimentary and metamorphic rocks are dealt with more adequately and, allowing for the limited scope of the book, the general treatment of the physical agents is good.

The historical chapters, based on the stratigraphy of North America and including sections on the development of life and also on the chief economic products of each system, are necessarily sketchy; nevertheless a broad picture of essentials is gradually built up. The book is not well adapted to the needs of British students, but teachers will find the method of presenting the subject to be of considerable interest.

For a quarter of a century Lahee's "Field Geology" has been a widely appreciated standard manual for field geologists and engineers. The first part of the book is concerned with the recognition and interpretation of geological structures and topographic forms. A particularly valuable feature is the careful discrimination (often well summarized in tables of criteria) between superficially similar phenomena which may be of diverse origins. The second part deals with such topics as methods of surveying, construction and interpretation of maps, geological computations and preparation of illustrations and reports. There are many tables of practical value and the bibliography and index are both excellent.

In the new edition, the fourth, much new material has been incorporated by revision and expansion, notably on the structures of igneous and metamorphic rocks, the analysis and classification of folds and faults, and sub-surface and aerial methods of surveying. The chapters on aeroplane mapping and geophysical surveying have been rewritten and enlarged to embody the chief advances made during the last decade. There is no systematic treatment of groundwater or water-supply problems, but the volume is already so long and so packed with useful information that it will probably seem ungracious to ask for more. The new edition may be cordially recommended to all practical geologists and mining engineers, and it should certainly be acquired for the shelves of every geological library.

PLASTICS AND THEIR USE

Plastics in Industry

By "Plastes". Second edition, revised. Pp. xiii+248+45 plates. (London: Chapman and Hall, Ltd., 1942.) 15*s*. net.

SOON after the close of the War of 1914–18 there began to be talk of the plastics industry. Few knew what this indicated, excepting that it was possible to take certain condensation products made from simple substances and mould them into permanent objects with the aid of heat. The progress made in the last twenty years has been amazing; a yard-stick for its measurement was afforded by successive British Industries Fairs. On the purely chemical side there have been developments of two types: the discovery and manufacture of simple substances to use as condensing agents, and the understanding of the theory and practice of condensing to form large molecules of the desired size. There is now an abundant literature on this subject.

The plastics industry is developing on the lines that one firm makes the condensation products and perhaps their raw materials, while another undertakes the moulding. It is this section which is becoming so widespread as the use of plastic materials increases. The book before us is devoted to the moulding industry and is written to give industrialists in general a picture of what plastics are and what can be done with them. The claim is that they are easily moulded into complicated shapes and can be given properties of outstanding advantage. The synthetic chemist has enriched the world with dyes, drugs, solvents and many organic substances in daily use. In plastics he has made a further step forward in providing materials of construction which compete with wood and metals.

There are two types of plastic based on different raw materials, namely, those which can be re-softened by heat and re-moulded, generally called thermoplastics, and those which remain rigid and hard when once moulded, known as thermosetting. The technique of their fabrication, a purely engineering industry, is becoming complicated. It includes blowing or shaping, extrusion through nozzles or dies, compression moulding and injection moulding.

The book describes the technique in sufficient detail and goes on to deal with the applications of the articles made in the engineering, chemical and electrical industries.

In these days when so much depends on aircraft, there is no need to emphasize the importance of light-weight materials, and plastics have become available for many unstressed and lightly stressed parts at one time made of light alloys. Plastics in aircraft construction have become a science and industry on their own.

What the modern motor-car owes to plastics is well known; more recent is the relation to the textile industry. We have at last, in 'Nylon', a wholly synthetic fibre made from highly complicated condensation products of a nature such that the final substance does have an affinity with protein. The 'Nylon' fibre owes much to the fact that at one stage of its manufacture it is cold drawn—yet another example of the co-operation between engineer and chemist.

The possibilities of plastics in the building and furniture industry are obvious: they will figure largely in the house of the future, provided the masses learn to take more care of what does not immediately belong to them.

The book goes into many other applications with just sufficient detail to illustrate the potentialities and whet the appetite of the reader.

Plastics have one great advantage, their raw materials are largely indigenous, so that the establishment of a virile industry in Great Britain depends on the chemists and the enterprise of the industrialists. It should develop to a very large and remunerative industry giving employment to a skilled person.

E. F. ARMSTRONG.

STARLING MOVEMENTS AND THE SPREAD OF FOOT-AND-MOUTH DISEASE

By DR. W. S. BULLOUGH
University of Leeds

A CONNEXION between the erratic and inexplicable occurrence of foot-and-mouth disease and the movements of wild animals has been suspected for a long time, and in the annual Reports of Proceedings under the Diseases of Animals Acts, published by the Ministry of Agriculture and Fisheries, frequent references are made to the possibility that certain outbreaks of disease were due to the presence in the infected area of unusually large numbers of such birds as rooks, gulls, or starlings. The first serious attempt to correlate the movements of birds with the spread of the disease appears to have been that of Stockman and Garnett[1], but their work was strongly criticized, mainly from an ornithological aspect, by Thomson[2]. They did, however, make the valuable suggestion that the only obvious way in which the disease can be transmitted over large distances, often apparently in a very short time, is through the agency of birds, and their ideas have formed a basis for a new survey of the problem now in press in the *Proceedings of the Royal Society*[3]. This survey has been made possible by a study[4] of the breeding behaviour of the British and Continental races of the starling, *Sturnus vulgaris* L., and it consists of a correlation of this new knowledge with an analysis covering nearly forty years of the records of foot-and-mouth disease in the British Isles and on the Continent.

The migrations and movements of all the species of birds studied by Stockman and Garnett have not been considered again in the present survey. Attention has been focused on the starling alone, as this species is extremely numerous, normally frequents and feeds on pasture land, and is closely associated with farms and with cattle. The birds, keeping together in large companies, excavate their food from the ground, and for reasons not yet explained, they prefer to feed in the immediate vicinity of the noses and feet of grazing animals and often perch on their backs. If the normal food source fails due to frost or snow, starlings commonly flock into the cattle sheds and feed in hundreds from the feeding troughs. Although there are other species of birds with similar habits to these, there is no other present in such enormous numbers and which moves about Great Britain in such large flocks.

The first problem to be considered is that of the introduction of foot-and-mouth disease into Great Britain. Unless a natural reservoir of disease exists in some wild species within the British Isles, it appears that such introduction must take place, because each epidemic is so vigorously suppressed, and it is possible that the virus may be imported by Continental starlings on migration in autumn. In this connexion it is important to note that the native British starling is almost entirely sedentary, and therefore cannot be concerned at this stage. Hundreds of Continental starlings have been ringed on the Continent in summer and recovered in the British Isles in winter, or marked here in winter and recovered in their native countries in the breeding season. Analysis shows that of ten birds natives of Norway, seven were reported in Scotland and only one in Northern Ireland and two in England, whereas of 563 birds coming from or going to Continental countries other than Norway, 559 were reported in England, Wales and Ireland and only four in Scotland. The numbers of marked birds moving between Norway and Scotland are unfortunately only small, but nevertheless it appears that the migrating Norwegian starlings tend to winter in Scotland while the other Continental starlings come to England, Wales, and Ireland. Probably two separate migration routes are used, the birds from the countries bordering the Baltic being prevented from entering Norway, and so crossing to Scotland, by the mountain chain which marks the western boundary of Sweden. This conclusion is significant because foot-and-mouth disease is rare in both Norway and Scotland, whereas it is common in England, Wales and Ireland and in such countries as Sweden, Denmark, Germany and Holland, whence come most of the starlings which arrive each autumn on the east coast of England. It is interesting to note that when an unusually large epidemic starts on the Continent it appears to spread to England at the autumn migration time. This was true in 1925 and 1926, and again in the autumn months of 1930 and 1932.

The spread of foot-and-mouth disease inside the British Isles may also be due to birds, and here again the starling has a striking habit, namely its tendency to roost communally in enormous numbers in a plantation or reed-bed. All the birds within about twenty-five miles of such a place fly there each night to sleep. Opportunities for the spread of a virus inside a roost are great as the birds pack closely together shoulder to shoulder, and next morning it is possible that the disease may be taken for many miles in some new direction. The strength of the urge for communal roosting varies with the seasons. British starlings indulge most strongly in the habit from June to December, in which month a close attachment to the nesting places begins. Immigrant Continental starlings roost communally from September to March, which is the entire period spent in the British Isles. The numbers of birds present in the roosts in each month of the year give an indication of the numbers travelling daily across the country, and therefore they may also give an indication of the probability that a disease will be spread. Counts were made each month of the numbers of starlings frequenting two roosts in the neighbourhood of Leeds, and the results were checked by observations on seven other roosts.

TABLE 1. APPROXIMATE AVERAGE NUMBERS (IN THOUSANDS) OF STARLINGS OCCUPYING COMMUNAL ROOSTS IN THE NEIGHBOURHOOD OF LEEDS.

1939										1940	
Mar.	Apr.	May	Jun.	Jul.	Aug.	Sept.	Oct.	Nov.	Dec.	Jan.	Feb.
10	1	4	25	35	15	25	50	65	70	35	30

These figures are compared in Graphs 1 and 2 with the monthly numbers (Table 2) of unexplained outbreaks of foot-and-mouth disease, and it is seen how close is the correspondence.

TABLE 2. NUMBERS OF UNEXPLAINED OUTBREAKS OF FOOT-AND-MOUTH DISEASE IN THE BRITISH ISLES BETWEEN 1900 AND 1937.

Jan.	Feb.	Mar.	Apr.	May	Jun.	Jul.	Aug.	Sept.	Oct.	Nov.	Dec.
42	30	19	16	8	12	22	15	31	54	53	47

Both graphs rise and remain high in the autumn when millions of starlings arrive from the Continent to reinforce the local population. Extremely large numbers of birds are then moving backwards and forwards across the country each day. The fall in both graphs from December to February may be correlated with the fact that at this time most adult

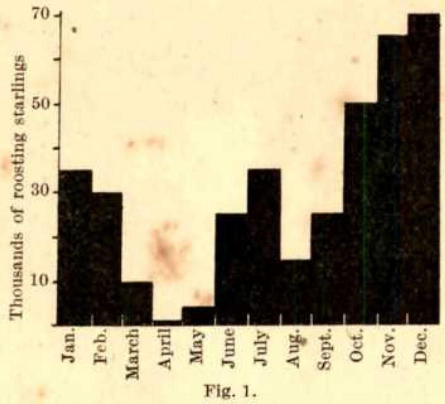

Fig. 1.

AVERAGE NUMBER OF STARLINGS OCCUPYING COMMUNAL ROOSTS IN WHARFEDALE IN 1939 AND 1940.

British starlings remain to roost in their nesting holes, so that the daily movements of birds are considerably reduced. In March the Continental birds leave for their breeding places, and the roosts, then mainly occupied by first-year and non-breeding males, reach a minimum size. In June the parents and newly fledged young return to sleep communally and both graphs rise steeply as big daily starling movements are resumed. A peak is reached in July to be followed by a fall which, at least in the case of Graph 1, appears to be connected with the serious weakening of the power of flight during the August moult of the flight feathers. An exceptional case was discovered of a bird which was hardly able to fly at all[5]. In September the new flight feathers are fully formed, the British birds again make long daily flights, and the first Continental birds arrive.

It was considered possible that if foot-and-mouth disease is brought into Great Britain from the Continent in autumn due to starling migrations, and if the birds (from countries other than Norway) arrive first on the east coast and only later spread right across England and Wales, the peak of the monthly incidence of disease might be earlier in the eastern counties than in the west. England was therefore divided into roughly equal eastern and western parts, Wales being included in the western part, and it was discovered that, in fact, the greatest monthly number of outbreaks occurred in the eastern area in October whereas the peak for the western area was not reached until November. Further, whereas in the western area the minimum incidence of disease was in April, in the eastern counties there was a small peak in that month possibly connected with the return journey across this area made late in March by birds from the western area.

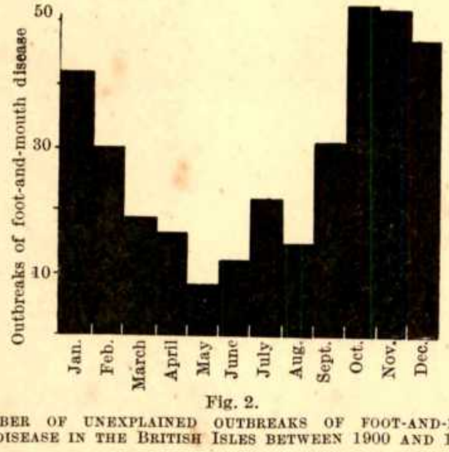

Fig. 2.

NUMBER OF UNEXPLAINED OUTBREAKS OF FOOT-AND-MOUTH DISEASE IN THE BRITISH ISLES BETWEEN 1900 AND 1937.

It has been shown that foot-and-mouth disease is most prevalent in the British Isles in autumn and winter when the starling population is at a maximum, and in order to test this correlation it was decided to study the monthly incidence of the disease in some northern country where the starling population is reduced or even absent in autumn and winter. Sweden was chosen as most suitable, and the numbers of outbreaks of disease from 1900 until 1937 were obtained through the generosity of Prof. H. Magnusson. Unfortunately, in the records no distinction was made between the primary unexplained outbreaks and the secondary outbreaks due to known causes. The figures in Table 3, therefore, refer to the total number of outbreaks, and only broad conclusions may be drawn from them.

TABLE 3. TOTAL NUMBER OF OUTBREAKS OF FOOT-AND-MOUTH DISEASE IN SWEDEN BETWEEN 1900 AND 1937.

Jan.	Feb.	Mar.	Apl.	May	Jun.	Jul.	Aug.	Sep.	Oct.	Nov.	Dec.
489	975	1396	1855	1810	1203	823	696	609	464	426	427

These figures are expressed in Graph 3, and it is immediately clear that this is a direct opposite to Graph 2 for the British Isles. There is a sharp rise in the incidence of foot-and-mouth disease in late winter, a maximum being reached in April when all the birds have returned from the south. Again, instead of a rise in autumn, the graph falls to a minimum in November and December.

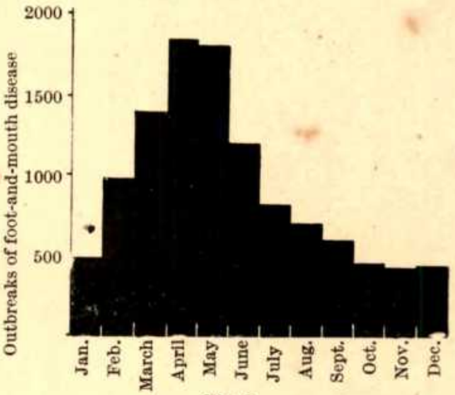

Fig. 3.

TOTAL NUMBER OF OUTBREAKS OF FOOT-AND-MOUTH DISEASE IN SWEDEN BETWEEN 1900 AND 1937.

One further line of evidence remains to be considered, namely, the geographical distribution of the starling and of foot-and-mouth disease in the British Isles. In 1932 and 1933, Marples[6] made a survey of the roosting places of the starling in Great Britain, and found that they are not usually located above an altitude of 600 ft. Of 285 roosts recorded only five were above that level. Marples considered that this is probably due to the fact that above 600 ft. there are, on the average, only rough hill pastures or heather moors, both of which habitats the starling tends to avoid. The positions of the primary unexplained outbreaks of foot-and-mouth disease were plotted to discover whether these also tended to occur below 600 ft., and it was found that of 270 outbreaks occurring between 1922 and 1937 only two were above that level. The value of this last correlation is not certain because, of course, most cattle are also found on lower land, and many of the sheep and deer which frequent the higher ground come down from the hills in the winter. Therefore, before the true significance of this correlation could be assessed it would be necessary to find the proportions of sheep and cattle above and below the 600-ft. level at all times of the year.

These various analyses provide striking, if only circumstantial, evidence of a connexion between the movements and distribution of British and Continental starlings and the incidence of foot-and-mouth disease; but there are certain facts contrary to this general conclusion which must be mentioned. In the first place, experiments with captive starlings have indicated the great difficulty of inducing birds to transmit the virus of foot-and-mouth disease, and it may be that some special condition, such as illness, is required before the bird can act as a carrier. In this connexion it will be noticed that although many millions of starlings must have entered and moved about the British Isles between 1900 and 1937, only 349 unexplained outbreaks of foot-and-mouth disease occurred in the whole period. A second point of difficulty is presented by the great epidemic of foot-and-mouth disease which appeared in Europe immediately after the period surveyed in Tables 2 and 3, and the numbers of these outbreaks, if included, would considerably alter the shape of Graph 3. In the autumn and winter months of 1938–39 there were almost as many outbreaks of foot-and-mouth disease in Sweden as in the whole of the previous thirty-eight years, and similar conditions prevailed all over the Continent. However, an epidemic of this magnitude would be expected to present abnormal features, and it seems that the spread of the disease northwards across Europe may have been due to unusual factors.

It is difficult to see how proof or disproof of a thesis that the starling is an important carrier of foot-and-mouth disease can be obtained, and certainly many factors other than the starling must be involved in greater or lesser degree. Latitude, weather, and several species of birds may exert an effect, and possibly also there exists in some species of wild mammal a natural reservoir of disease[7] although, if this last contention is correct, it is difficult to understand why many more outbreaks do not occur. At the present moment it does not seem possible to do more than put forward the suggestive but inconclusive evidence.

CANTEEN FEEDING

By F. LE GROS CLARK and DR. N. W. PIRIE

MUCH has been written, in Nature and elsewhere, on the relative merits of research that has absolutely no practically useful end in view and of research that it is hoped will lead to improvements in practice. The latest meeting organized by the Nutrition Society was held on May 30 to consider "Problems of Collective Feeding in War Time", and it gave invaluable evidence on the ease with which nutritional and biochemical research could produce immediately useful results without coercion of the research worker or any sacrifice of interest in the more fundamental aspects of science. Few research workers can have attended the meeting without being impressed by the extent to which pure scientific research was needed as a preliminary to the solving of the very practical problems of food distribution and cooking. If more meetings can be held at which men of science have the opportunity of learning about the problems that arise in practice, it is very probable that much of the necessary practical research will in fact get done with no greater interference with the freedom of choice of the individual research worker than we had in the last years of peace. It is greatly to be hoped therefore that the Nutrition Society will organize other conferences along the lines of the one that has just been held.

Squadron-Leader J. Salmon described the standard conditions in the Royal Air Force. An aircraftman's mess can serve a thousand meals at a time; it is often necessary to have two sittings for meals because of the unanticipated growth of a station. The mess is under the control of a catering officer, if there are more than six hundred men on the station, and a mess committee; close attention is paid to the general wishes of the eaters, for no choice of food is available. The amounts of rationed food drawn by the catering officer are rigidly controlled, and he is encouraged to draw his full rations so that an average of 3,500 calories a day for each man and 2,800 for each woman can be maintained.

Experience has shown that, to avoid waste, it is best to serve moderate helpings and allow those who wish more to get further helpings. In the discussion there was agreement that catering in the R.A.F. is better than in the other Services, but that there is still room for improvement. The old adage "God sends the food but the Devil sends the cooks" seemed to sum up the view of several critics, and the sensible suggestion was made that cooks should be paid extra if only for the reason that they could then lose pay if they cooked badly. Other speakers mentioned the difficulty found in getting women with cooking experience in civil life to take up cooking in the W.A.A.F.s. in spite of the extra pay that is in fact given.

Works canteens and British Restaurants are presented with a somewhat different problem, for they do not have a guaranteed clientele but have to attract diners by the quality of the meals served. How successful they are at doing this is shown by Lord Woolton's opening statement that 94,000,000 meals a week are now served "off the ration", and by the great extension of the works canteen system. Miss I. M. Clift said that there are now 7,500 industrial canteens—five times as many as in 1940—and she described vividly the methods used in her canteen to popularize the eating of foods to which the workers were unaccustomed. The mass-psychological aspect of these canteens was also referred to by Miss M. C. Broatch in her paper on school canteens. The first principle is that a novel food should appear as an extra rather than as an alternative and that at the beginning it should be in short supply; furthermore a choice of meats and vegetables on each day and a different choice on each day of the week is an advantage. It is interesting to learn that 40 per cent of the workers in one factory choose wheatmeal bread rather than white when a choice was offered, for before the introduction of the 85 per cent extraction loaf it was often stated that the British public insisted on white bread.

Miss M. Abrahams described measurements made on the meals served in forty-one British Restaurants. The calorie value ranged from 494 to 1,797 per meal; only six gave more than 1,000 calories. The prices ranged from 8*d.* to 1*s.*, and the calories per penny from 41 to 163, with only seven Restaurants giving more than 100. Part of this variation is deliberate, for Dr. M. Pyke had already said that the Ministry of Food tried to get bigger meals served in those Restaurants that tended to cater for heavy workers, but it was suggested that much of the variation was unintentional and to be deplored. The Londoners Meals Service makes every effort to serve children with a uniform balanced meal of an agreed protein, fat and carbohydrate content, and this organization is now supplying London school-children with fifty thousand meals a day. These meals contain as much meat as the meal that works canteens serve to heavy workers; there has been some opposition to this practical appreciation of the fact that a growing child needs more protein than a normal adult, but headway is being made in most areas.

In considering the nutritive value of the food served in these various canteens most of the speakers concentrated on ascorbic acid. This preoccupation with only one out of some hundred known essential metabolites was deplored by several speakers, notably Squadron-Leader T. F. Macrae and Mr. A. L. Bacharach, but it is presumably inevitable on account of the greater difficulty with which the other minor dietary constituents can be estimated.

It was clear in the discussion of most of the papers that the academic research workers tended to turn automatically to calories, protein and ascorbic acid as the criteria of a good meal. This suggests that work should be undertaken to see whether an ordinary British meal that is adequate in these three respects is likely to be adequate in other respects also, for, if this were true, it would greatly facilitate the problem of inspection.

The various factors that lead to unevenness or inadequacy in the consumption of ascorbic acid were considered in some detail. In the first place a better selection of vegetables could be planted and more care could be taken to ensure that green-stuff is available all the year round. Prof. J. R. Marrack pointed out that, in the bulletin issued by the Ministry of Agriculture, kale is scarcely mentioned whereas considerable attention is paid to parsnips. The former is a valuable source of ascorbic acid in the spring whereas the latter is almost valueless from this point of view. With green vegetables speed is essential in distribution; a cabbage that has taken 3–7 days in getting from the field to the kitchen will have lost half its ascorbic acid in the process. The potato is more stable, but there is loss during the correspondingly longer period for which it is generally stored.

Many speakers referred to the eating of vegetables raw as a means of avoiding the losses that are often entailed in cooking. The consensus of opinion seemed to be that this would not altogether solve the problem and that it might lull the caterer, who does not consider closely what weight of material is actually being eaten, into a state of false confidence. Raw vegetables are bulky and, if served up as a salad with whole leaves, very little is actually eaten. If, on the other hand, the bulk is reduced by grating, ascorbic oxidase is liberated from the damaged leaf cells and causes serious destruction of the ascorbic acid. This destruction can be greatly minimized by shredding or slicing instead of grating, for in these circumstances the proportion of damaged cells is smaller. Even if the vegetable gets into the diner's mouth with its ascorbic acid undiminished all is not necessarily well; for Dr. M. Pyke quoted an experiment in which 19 per cent of the ascorbic acid in a sample of sliced raw cabbage was destroyed in thirty seconds' chewing and 29 per cent in sixty seconds. In the subsequent discussion it was pointed out that further destruction probably took place in the alimentary canal before absorption had taken place and that, although it is likely that the destruction is due to enzyme action, this should have been confirmed by a similar experiment with cabbage in which the enzyme had been destroyed by boiling under proper conditions.

When green vegetables are being cooked what is to be aimed at is the most rapid possible destruction of ascorbic oxidase and the smallest possible loss of minerals and ascorbic acid in the water used for boiling. Many suggestions for achieving these two desiderata were made. Macrae said that the gradual addition of quartered cabbages to the boiling cauldron of water, at such a rate that the temperature never fell below 85° C., led to the preservation of most of the ascorbic acid; whereas 80 per cent was destroyed if all the cabbage was added at once so that the whole mixture fell to 60° or 70°. Dr. R. G. Booth described the successful avoidance of this loss in some British Restaurants by using a large number of small pots that can be heated rapidly. Dr. L. W. Mapson said that a smaller volume of water could be used for cooking if the vegetables were shredded first and suggested that the outside leaves of cabbage might be boiled in the water first and then removed before adding the shredded cabbage. By this means the cooking would be done in dilute ascorbic solution. The value of this suggestion depends on a number of quantitative factors that cannot be assessed on the spur of the moment in a meeting and there was no further discussion of the point. Several speakers pointed out that the extraction of ascorbic acid and minerals was only objectionable if the water were then thrown away but that it did not matter if the same water was used over and over again for boiling vegetables or if it was afterwards used for making soup or gravy; both procedures are in fact followed in many establishments.

If the problem of cooking large amounts of vegetables without serious loss of ascorbic acid has been surmounted, there is still an opportunity for loss if the food is kept hot for long before it is consumed. Mr. F. Le Gros Clark described the Russian pioneer experience in this field. In 1925 central kitchens sent out cooked food, in insulated containers, to factories, but this system was given up progressively from 1931 and thereafter they sent out food prepared and ready for cooking. This change is in accordance with British experience during the last few years and several speakers condemned the insulated container. Dr. Pyke found that after 2½ hours about half the ascorbic acid present in cooked greens or potatoes had been lost, but he pointed out that the final product might well be better than badly cooked vegetables prepared on the spot. It is clearly impossible to do all the cooking in a large canteen or mess immediately before the meal is served; and the cooks and catering officers should therefore be advised which foodstuffs are but little damaged by being kept hot until the rest of the meal is ready and which are seriously damaged. Several speakers mentioned the readiness with which scientific advice on these matters was accepted by cooks and catering officers.

The proceedings of this most successful conference fell into three parts: first, the organization and method of control of canteen feeding; secondly, the stability of ascorbic acid under the conditions of large-scale cookery; and thirdly, a buffet lunch in the production of which at least some of the principles on which there had been substantial agreement seemed to have been borne in mind.

DEGENERATION AND RELICT ADAPTATION

By PROF. JULIAN HUXLEY, F.R.S.
Zoological Society of London

RECENT advances in biology have shed considerable light on the evolutionary fate of originally adaptive structures which have since become functionless. It is a commonplace that in the great majority of animals such organs degenerate and either disappear entirely or become vestigial, while often showing excessive variability. This tendency to degeneration (and excess variation) of functionless organs appears to be automatic in sexually reproducing organisms with any considerable degree of outbreeding, like the great majority of higher animals. In such cases, as Muller[1] has pointed out, mutation-pressure alone will tend to cause useless organs to degenerate. Sewall Wright[2], while agreeing with this view, believes that a more important factor operating in the same direction is the prevalence of multiple-factor (polygene) systems of genes with multiple (pleiotropic) effects, in the genetic make-up of organisms. Wherever this is so, "the evolutionary changes in a system of genes, some bringing increased development and others reduced development in those parts of the organism which are under direct selection, should have a net effect on *indifferent* parts in the direction of reduced development". Further, when linked polygenic systems exist (that is, polygene systems consisting of one or more sets of genes which show genetic linkage with each other) and two such systems are lodged in the same chromosome or chromosomes, then anything which promotes change in the one will, by virtue of the resultant general recombination, promote change in the other. Thus, if selection is acting to alter the main character controlled by one such system, while the character controlled by the second is selectively neutral or useless, the resultant recombination will 'break up' the useless character, and in virtue of the obvious tendency of change to be towards decreased efficiency unless kept up to the mark by selection, this will promote degeneration of the useless feature. Degeneration of useless organs is thus genetically inevitable, partly as the direct effect of mutation pressure, partly indirectly as a by-product of selection acting on polygene systems with multiple effects.

None of this reasoning, however, should apply in the case of organisms which do not practice outcrossing, that is, species (mostly plants) with complete obligatory self-fertilization, parthenogenesis or apomixis, or exclusively vegetative reproduction. For one thing, in them the recombination of 'loss' mutations is no longer possible, and in its absence degeneration should only be able to proceed with extreme slowness. Furthermore, since many loss mutations are deleterious to general viability, it seems probable that they need buffering to survive, and for this again recombination is necessary, so that where recombination is impossible, mutant characters of this type will be automatically eliminated.

The result should be the opposite of that found in most higher animals, namely, the complete or almost complete persistence of originally adaptive structures in spite of their having become wholly functionless—'relict adaptations', one might call them.

The most natural place in which to look for such organs would be among the floral mechanisms of such higher plant species as have abandoned outcrossing for compulsory self-fertilization or apomixis. At first sight there would appear to be numerous examples of this. For example, in various genera of Compositæ such as the dandelions (Taraxacum) and the hawkweeds (Hieracium), there exist a number of forms which appear to produce all their seed by obligatory apomixis. Yet in spite of this they continue to produce an abundance of showy flower-heads, obviously adapted to attract insects.

It might, however, be objected that the persistence of these erstwhile adaptations was due to the short time which had elapsed since the type had changed over from normal sexual reproduction to apomixis. We know of such instances in animals. For example, in the spruce sawfly Gilpinia (Diprion), there are two extremely close 'biological races' or species of which one shows obligatory parthenogenesis, while in the other parthenogenesis alternates with sexual reproduction (Balch, Reeks and Smith[3]). There can be no doubt that here obligatory parthenogenesis is a very recent acquisition, so that we should not be surprised at the persistence of organs subserving sexual reproduction, such as the spermatheca in the females, or the testes in the occasional but functionless males produced. However, in Taraxacum, Dr. W. B. Turrill informs me that apomixis may well date back at least ten thousand years, to the period when the ice was retreating.

On the other hand, there is a more serious objection to considering flower-heads such as those of dandelions as relict adaptations, namely, the presence of numerous 'correlated characters' which might still be regarded as having functional significance even after the main (entomophilous) function of the capitulum had been lost. Various parts of the mechanism must be useful in providing the developmental scaffolding for the production of the pappus, which is, of course, highly adaptive in regard to the dispersal of the (apomictic) seeds, and the long ray florets still play a part in protecting the central parts of the head during its closure at night, though this protection itself may perhaps be a relict adaptation, as it probably concerns the pollen. However, such considerations do not seem to apply in some of the obligate apomicts in grasses, where the floral mechanism was adapted to anemophilous cross-pollination, and yet survives its loss of function.

Still another complication exists, in the shape of the segregation which we now know to occur in various apomicts (Crane and Thomas[4]). This is due to crossing-over, the apomictic embryo presumably arising after the first meiotic division. This asexual segregation may well have been responsible for some of the swarms of forms found in apomictic groups. It will also give a certain amount of recombination, which in its turn will facilitate a certain amount of degeneration.

Another apparently good case, unless the change of reproductive method is very recent, is provided by the coral-root *Dentaria bulbifera*, which reproduces entirely by bulbils, but continues to make the unnecessary gesture of producing obviously entomophilous flowers, which further do not seem to have any subsidiary non-sexual function as in Taraxacum.

The complexity of the phenomena is well illustrated by the lesser celandine, *Ranunculus Ficaria*. Here, as Marsden-Jones[5] has shown, two varieties co-exist in Britain, one reproducing sexually, mainly by cross-pollination, the other (var. *bulbifera*, a tetraploid form) mainly vegetatively, by means of bulbils. However, in this latter form a small percentage of viable seed may be produced, apparently by cross-pollination. Furthermore, the mean width and number of its petals and the mean number of its stamens are slightly reduced. If this should not be a consequence of tetraploidy, it is evidence of incipient degeneration of these relatively useless organs—a degeneration made possible by their small residual function. Dr. W. B. Turrill tells me that similar floral degenerations are associated with apomixis in Alchemilla, indicating that here too some degree of recombination is still possible.

Obligatory self-pollination would bring about the same genetic result as obligatory apomixis. Here, however, the difficulty is to find satisfactory examples, since in the great majority of cases self-pollination is not completely obligatory and a certain fraction of seeds result from outcrossing. Thus the orchis *Epipactis leptochila* is normally self-pollinating, but cross-pollination appears to be possible for a brief period (Godfery[6]). The closely related *E. latifolia* is exclusively cross-pollinated. However, Dr. Mather informs me that the common tomato (*Solanum lycopersicum*), which has been investigated for many years at the John Innes Horticultural Institution, shows no cross-pollination at all in Great Britain (save in one anomalous structural variety). Yet the obviously entomophilous flowers persist in spite of this, and in spite of never being visited by insects.

In some strains of cereals, the frequency of cross-pollination is only 2 per cent, and it would seem that a rate as low as this should enormously reduce the speed at which degeneration might occur; but in other strains the cross-pollination rate may be considerably higher. The fact that forms like certain species of Taraxacum have abandoned incomplete self-pollination for obligate apomixis would indicate that the amount of cross-pollination previously possible was interfering with the immediate advantages obtainable by reduced outbreeding.

A prima facie case thus seems to be made out for the failure of degeneration to occur, with the consequent persistence of 'relict adaptations', whenever cross-breeding is absent and perhaps when it is markedly reduced. However, the phenomena are often exceedingly complex, and the interpretations of floral mechanisms by earlier writers have often been coloured by a somewhat uncritical armchair Darwinism. Thus, a good deal more investigation is required before this interesting theoretical deduction can be regarded as confirmed.

In conclusion, I would like to thank Prof. E. J. Salisbury, Dr. W. B. Turrill, Mr. John Gilmour, Dr. C. D. Darlington, Mr. E. B. Ford, and especially Dr. K. Mather, for their help and advice.

MODERN SCIENCE AND THOMAS HOBBES

By A. E. BELL

St. Marylebone Grammar School, London

THREE hundred years ago appeared the first of Hobbes's chief philosophical works, his "De Cive". The "Leviathan" followed in 1645, the "De Corpore" in 1655 and the "De Homine" three years later. Few scientific men would claim to read these works to-day, and in the history of science Hobbes is usually given little notice. 1642 is famous rather as the date of Galileo's death and Newton's birth. The scientific movement was at this time gaining momentum; scientific societies were springing up in Florence, London and Paris and gaining the support of men of wide interests as well as the 'mathematical heads'. Evelyn and Pepys, Chapelain and Perrault illustrate the general appeal which science then made. "This is the age," wrote Power, "wherein methinks, philosophy comes in with a spring tide."

This natural philosophy was not regarded as threatening existing ideas; poets and divines were among those who hailed the discoveries of science as opening out new vistas to the human spirit. Bacon's new world indeed seemed to be in sight. "It is the great prerogative of Mankind above other creatures," wrote Hooke in 1665, "that we are not only able to behold the works of Nature, or barely to sustein our lives by them, but we have also the power of *considering, comparing, altering, assisting* and *improving* them to various uses." Science was regarded as a study of phenomena which could yield a measure of control over man's environment. Even in the seventeenth century, however, it was becoming clear to men like Huygens, Newton and Boyle that practical control was to be looked for rather as the inevitable by-product of the amassed theoretical knowledge—the 'intellectual control'—than as the immediate aim of research.

From all this inquiring and empirical spirit of the seventeenth century Hobbes came to be alienated by an unfortunate though perhaps inevitable combination of character and circumstance. For years he was on close terms with Mersenne and some of the greatest natural philosophers of the Continent; he was a friend of Bacon and he met Galileo. But Hobbes's acquaintance with the men of science came rather late and his studies never adequately prepared him for active work, especially in mathematics. Yet, like his contemporary Descartes, he felt a desire to generalize the conclusions of science where possible and to demonstrate its relation to other fields of knowledge. Descartes had the merit of stimulating research and of being a mathematical genius. Hobbes had far less equipment and committed inexcusable blunders in his attempted innovations in science and mathematics. Nevertheless we have in his best work, as Prof. Burtt has remarked, "the first important attempt to apply the new assumptions and method of Galileo universally". Unfortunately, Hobbes's errors were relentlessly exposed by Wallis, a great mathematician and a formidable opponent. The feud which developed lasted to the end of Hobbes's long life and effectively alienated him from the English men of science. The members of the Royal Society, he suspected, were banded together against him, and in time, polemic and ridicule and the resort on both sides to political accusations made this almost the case.

The result was to draw from Hobbes some radical criticism of the fundamental ideas employed in scientific writing. Hobbes carried to its logical conclusion the criticism of secondary qualities begun by Galileo. Denying the real existence of all secondary qualities such as colour, sound and odour as Galileo had done, he went on to assert that space and time themselves were mere 'phantasms'. He made a distinction between space and geometrical extension, the latter only, in his view, being an essential characteristic of a body. Time for Hobbes was "the phantasm of before and after in motion": "The present only has a being in Nature; things past have a being in the memory only; but things to come have no being at all . . ."

The men of science were critical of *a priori* speculations but Hobbes's attacks enforced the use of words in a narrow scientific sense, a change for which Hobbes will always be held as partly responsible. His own style was whetted and sharpened on the grindstone of scientific and logical polemic. The mathematical concept of featureless time and the scientific notion of cause were among the ideas which became more explicit. Over the definition of cause Hobbes may be held to have forestalled Hume, for he swept aside all notion of a final cause and equated cause with the sum of the antecedent conditions.

Hobbes's determination to be clear-headed made him a convinced nominalist. Particular objects only had a real existence, and words corresponded to mental images of things. Reasoning, he supposed, was explicable as a succession of images the order of which resulted from the operation of forces of the same nature as those operating in the world of corporeal things. Carried to an extreme, it could be held that true propositions about the world might be evolved out of the proper use of a symbolic language. Such a language was sought by Bishop Wilkins, but many were sceptical about Hobbes's materialistic explanation of the mind and limited mechanical causation to the physical world. For Hobbes the whole of Nature was a closed system in which the changes of configuration were completely determined by the laws of impact of the ultimate particles of which everything was composed. In the eighteenth century Condillac continued Hobbes's materialism. Science, in his view also, was only "une language bien faite". It is worth remembering that Diderot was one of Condillac's most celebrated pupils.

At this point it should be stated that the seventeenth century men of science were more influenced by Gassendi than by Hobbes. Earlier than the English philosopher, he put forward a materialistic atomism of a sufficiently crude nature. Through Huygens and Boyle, however, his ideas were spread and became especially important in chemistry. The great developments in chemistry came in the second half of the eighteenth century, and this, under the leadership of Diderot and the Encyclopædists and of Voltaire, was a materialistic era. Hobbes, though his position was fundamentally similar to that of Gassendi, had little influence over contemporary men of science. He professed great contempt for their ideas and even attacked their empiricism: "Experience concludeth nothing universally". It may be remarked that Galileo was not primarily an experimentalist and that the attitude to experiment had undergone some change with the growth of the scientific societies. Nothing illustrates Hobbes's dictum better than the contents of his "Dialogus Physicus sive de Natura Aeris" (1661) written in criticism of Boyle's work "New Experiments Touching the Spring of the Air" (1660). Hobbes there claimed that he had years before derived all Boyle's conclusions by reasoning from first principles. The weakness of such a position was not apparent to him; he did not see the force of the Royal Society's motto *Nullius in Verba* adopted a few years later. Because of this lack of comprehension and the obstinacy with which he defended his attitude, Hobbes, even in his advancing years, was an object of ridicule to Hooke and others. According to Hooke, writing of an encounter with Hobbes at a telescope-maker's, the philosopher was found "to lard and seal every asservation with a round oath . . . to have a high conceit of his own abilities and performances, though never so absurd and pitiful, etc." Hobbes, he said, asserted "that a common spectacle glass was as good an eye-glass for a thirty-six foot glass objective as the best in the world, and pretended to see better than all the rest, by holding his spectacle in his hand, which shook as fast one way as his head did the other, which I confess made me bite my tongue"[1].

Hobbes's contribution to scientific thought, however, has been important in spite of his professed indifference to scientific studies and his personal hostility to the English men of science. By trying to reduce all phenomena to the one cause of material impact between ultimate particles, he carried to an extreme a 'legitimate' materialism employed by the scientific men themselves. The need of other causal mechanisms, notably wave theories of sound and light, at first weakened the claims of such a view. It became clear that the scientific mode of *cause* is *force* and of this there appeared to be many kinds. It was only with the development of the concept of energy and work done that a return to a unified scheme appeared possible.

Huygens in 1693 gave the first clear statement of the principle of conservation of energy in mechanical systems[2], and the idea was developed by Daniell Bernoulli and Thomas Young. Rumford, Gay-Lussac, Sadi Carnot and Julius Mayer then paved the way for Joule's establishment of the general law of conservation of energy. The publications of Kelvin and Helmholtz popularized the concept of energy while Coriolis and Poncelet completed the system of physics required in engineering by introducing the term *work*. By the end of the nineteenth century it seemed as if the cycles of matter and energy were closed; the outlook of Hobbes had returned. So long ago as 1780 Lavoisier and Laplace had shown the equality of the heat generated by oxidation of carbon inside and outside the animal body. With the successful extension of physical and chemical principles to biology in the nineteenth century, it began to look as if the closed cycles existed indifferently in the organic and inorganic worlds.

Insufficient attention seems to have been given to the intellectual influence of chemistry in the nineteenth century. This was in fact the dominant science in industry after about 1860, and it was difficult to resist the suggestion that it was the science which could throw most light on the ultimate nature of matter. The stereo-chemical theory built up Pasteur, van't Hoff, Kekulé and others, for example, encouraged a visual imagery which all subsequent research proved to be correct in essentials. There seemed to be little doubt about the material nature of molecules; such work as that of Perrin disposed of that. Indeed the whole tradition of chemistry is materialistic, and experiments such as those on the artificial transmutation of elements are most commonly treated from this point of view. The problem of steric hindrance is perhaps the best example of the old outlook coming into contact with the new.

It is well known that chemists tend to adopt materialistic forms of physical entities ("when chemists talk about electrons they use a different language from physicists"); and if this is true to-day, it was so much the more difficult to escape from materialism in the nineteenth century. "For no man can live in the external truth among acids and salts", wrote Stevenson, "but in the warm phantasmagoric chamber of the brain with the painted windows and the storied wall". Stevenson could not have anticipated the phenomenalism of Mach and Karl Pearson which averted this antithesis. This was the view that the doctrine of determinist mechanism only applies to the abstract entities provided by logical analysis. Phenomenalism has never been adopted universally by scientific men, and in the nineteenth century the rift between science and philosophy encouraged the retention of a naïve realism.

Now that men of science show a renewed interest in certain philosophical problems, new opportunities have arisen for investigating the consequences of adopting the phenomenalist or realist position. The limitations of a method of abstraction would appear to incline one to phenomenalism. The only point on which one finds substantial agreement among scientific writers is that science can give us only a network of relations, and the search for the ultimate nature of substance is likely always to be fruitless. We discover relations, but the *relata* are defined by the relations and nothing else. In spite of this, arguments are adduced by some writers to support a scientific form of Berkeleyan idealism. The cycles of determinism which chain the mind are then broken by invoking a form of Heisenberg's uncertainty principle which has not yet gained universal approval. Human aim and value appear to be permitted simply because, as J. W. N. Sullivan explained, the cycles of determinism at present exist only in what is called 'field' physics. In the remainder of phenomena one supposes the quantum jumps are indeterminate in the sense that they cannot be fully predicted. As is well known, this is not to say they are outside any causal nexus, for we know the set limits of the effects.

The result is bleak and cheerless enough as the basis of a 'humanistic' outlook. Ethical and æsthetical considerations may still be valid, but they seem to be left over with a rather apologetic air. The whole position is Hobbesian: science, instead of being an instrument for reducing our apprehension of the world to forms providing increased control, is regarded as disclosing the nature of an objective and pre-existent reality "in its linkage to consciousness". Because there are difficulties in the old 'spectator' theory of observation, the mind is enmeshed in the determinist (or indeterminist ?) scheme. If one favours ultimate determinism it is easy for the ordinary man to relapse into pure Hobbesian materialism; if one seriously tries to adopt some kind of objectivized chance, the character of Nature appears lunatic and its 'order' is only another of those illusory ideas which need exposing. On either basis it is difficult to see how science can intellectually be other than an obstacle to its own application to ethical ends. Both in education and in adult thought this is surely the greatest problem of modern times.

GEOPHYSICAL METHODS IN GEOLOGY

A JOINT meeting of the London and Home Counties Branch of the Institute of Physics and the Geological Society of London, held on April 22, provided a useful review of the principal geophysical means now available to supplement the routine methods of geological survey. Prof. O. T. Jones opened the meeting with a brief account of the four main types of geophysical survey, which measure respectively the ground resistivity, the rate of transmission of an artificial seismic vibration and the gravitational and magnetic fields at the surface. He stressed the importance of close co-ordination between the two sides of the subject: geology might indicate the probable materials and structures, but confirmation of their actual existence and a closer estimate of their position could in many cases be best obtained by geophysical means.

It was clear that no general preference can be given to any one method. Each has its own range of suitability and its limitations, some of which were outlined in Dr. J. M. Bruckshaw's contribution. His warnings might perhaps be specially recommended to the notice of non-physicists, for complaints as to the 'failure' of geophysics have not uncommonly arisen from the quite impossible expectations put forward by uninformed critics. There are at least as many inaccessible problems in geophysics as in geological surveying; fortunately, they are not the same problems in each case.

The principal limitations arise from the necessity for adequate physical differences between the rock masses, and from instrumental difficulties. Dr. Bruckshaw pointed out that gravitational and magnetic surveys are largely differential, depending upon local irregularities in the field, produced by discontinuities in the geological structure. Thus they are particularly adapted for detecting faults, boundaries, etc., while the presence of a uniform flat-lying bed would only produce zero (or constant) anomaly. But in practice some of the other methods have been used differentially to locate discontinuities even if the exact interpretation of the records is obscure. Another, and very interesting, point was the contrast between the Eötvös torsion balance and the gravimeter: for the former the values observed depend upon the inverse cube of the depth; for the latter, upon the inverse square. If the size of the structure increases proportionately with the depth, the effect to be observed with the torsion balance remains the same whatever the depth, while with the gravimeter the effect increases with the dimensions. Thus the torsion balance is in this respect better suited for shallow structures.

First-hand accounts of geophysical work in the field were given by Dr. D. T. Germain-Jones, who dealt with seismic exploration in Iran, and Dr. A. F. Hallimond, who described the magnetic work of the Geological Survey of Great Britain.

In using the seismic refraction method in Iran, the recording instruments were placed along an arc at about ten miles from the explosion point. The object of the survey was to locate an anticline believed on geological grounds to exist in the oil-bearing Asmari Limestone, which is concealed beneath the Lower Fars Series. This first conclusion was not confirmed, but further seismic observations to the south-west led to the discovery of an anticline in the limestone, concealed beneath a syncline in the surface rocks.

---

[1] "Œuvres Complètes de Christian Huygens", 4, 381.

[2] *ibid.* 18, 554

This was confirmed by drilling, at a depth in agreement with the geophysical estimate, but only half that expected from neighbouring geological data. The peculiar structure is believed to be due to plastic deformation of the Lower Fars beds, which have been squeezed out above the Asmari anticline and thickened on either side.

The Geological Survey of Great Britain has employed magnetic methods at intervals since 1928. The range is restricted by the non-magnetic nature of most sedimentary rocks, but on the other hand the same fact allows a particularly satisfactory investigation of any underlying magnetic formations. A striking example of this was provided by the Survey mapping of the Melton Mowbray magnetic anomaly. The resulting contoured vertical force map bore practically no relation to the surface geology (Lias and Trias) but showed a remarkable magnetic 'high' area, with subsidiary ridges, such as might be due to igneous masses in the floor of older rocks. As a well-known French writer has observed: "la géophysique voit flou"; from east to west the outlines in the magnetic map become sharper until a system of ridges with east-north-east trend links up with the anomaly due to the exposed intrusive igneous mass at Mount Sorrel. The estimated depth of the floor is from 1,500 ft. to 500 ft. across the Melton anomaly.

Oil geology has afforded perhaps the most spectacular examples of success in geophysical exploration. Indeed, the value of the new oilfields discovered has tended to obscure the large number of explorations carried out on equally adequate grounds but which happened to yield negative results. They are sometimes described as failures, but they are in reality an essential part of the research. Obviously, researches cannot be limited entirely to 'successful' results, yet in the larger commercial departments programmes are designed in the expectation of only a few per cent of even moderately 'successful' results.

A clear account of some of the outstanding geophysical achievements in oil geology was contributed by Prof. V. C. Illing. Here the geological structures are chiefly anticlines or domes, and the principal methods employed are (1) seismic reflexion, for gently sloping structures, (2) torsion balance and seismic refraction, for steeper-sided salt-dome structutes, (3) gravity, refraction and reflexion in faulted and folded areas. Prof. Illing again stressed the need for co-operation in work which has for its ultimate object the presentation of a picture that is geological rather than physical. In conclusion, he described the successful employment of the Schlumberger method for correlating strata in boreholes. Electrodes are lowered down the boreholes and the resistivity of the adjacent rock is determined at intervals and plotted as a profile characteristic of the strata passed through. Very striking sets of profiles from groups of boreholes were shown, but caution was indicated since the results are affected by the methods of boring used, especially the nature of the mud; and the resistance of the rock itself may have widely differing values according to the presence of interstitial oil or saline waters.

To sum up: the meeting once again indicated the wide use now made of geophysical methods, and their acceptance in fact as one of the most important tools of geological research. The restrictions in their use are at present largely due to their relative novelty and rather high cost, which in Great Britain has tended to restrict their employment to commercial enterprise.

OBITUARIES

Captain John D. S. Pendlebury

CLASSICAL and prehistoric archæology suffer a severe loss in the death, during the invasion of Crete, of Captain John D. S. Pendlebury. He was the son of Herbert S. Pendlebury, a well-known London surgeon, and was educated at Winchester College and Pembroke College, Cambridge, where he held an exhibition and represented the University, and also England, in the high jump in 1926–27. As an undergraduate he showed already the high promise in classical scholarship and in archæology which he fulfilled in later years, and, on graduating in the first class of the Classical Tripos, he was awarded the School Studentship in the British School of Archæology at Athens (1927–28) followed by the Macmillan Studentship in 1928–29. He took part in excavations on prehistoric sites in Macedonia, and at Armant and Tell-el-Amarna in 1928 and 1929. This combination of Ægean and Oriental interests enabled him to put together in *Ægyptiaca* (1930) a 'corpus' of scarabs and other objects of Egyptian workmanship found on prehistoric sites in Greek lands, and he projected, with his scholarly and accomplished wife, a similar record of Ægean objects found in Egypt.

In 1930, Pendlebury was appointed curator of Knossos, in succession to Duncan Mackenzie, who had for many years been the principal assistant of Sir Arthur Evans. Here was a post which gave full scope to his abilities, for he was a persistent traveller and field-observer, and had the genial temperament which endeared him to all classes of Cretans. At Knossos itself there was still much to be done: supplementary excavation to clear up obscurities, reinforcement of repairs and precautions against weather damage to the 'Palace'; the preparation of a much-needed "Handbook to the Palace of Minos" (1933); and the classification, storage and calendaring of a very large accumulation of potsherds and other objects not needed by the Candia Museum, and indeed indispensable for minute study of the ruins. His intimate knowledge of the whole island found record in a larger handbook of the "Archæology of Crete" (1939).

It was part of the original arrangement that Pendlebury should continue during the winter months his direction of the Egypt Exploration Society's work at Tell-el-Amarna, but by 1934 the Egyptian and the Cretan duties had begun to conflict, and to the general regret Pendlebury resigned the curatorship of Knossos. For unforeseen reasons, however, the Egyptian work came to an end, and he found it possible to devote himself in his private capacity wholly to Cretan archæology. His memoir "City of Akhenaten II", published in 1933, gives a full account of his work in Egypt.

Thenceforward, with his wife, and a succession of younger students of the British School of Archæology, Pendlebury carried on minute and intensive exploration in the Lasithi highland, below the Dictæan Cave at Psychro, already excavated by the School; and the results of this have now appeared in a separate volume of the School's *Annual* (38, 1937–38) as well as current reports in earlier volumes; a remarkable record of the human occupation of this secluded region from the early Bronze Age until it became a refuge and last fortress of the Minoan people after the Iron Age invaders had conquered the lowlands of Crete.

When the War came, Pendlebury received a commission in a cavalry regiment but remained in Crete as British Vice-Consul and was able to render very valuable services through his intimate acquaintance with the country and the people. Rumours of his death during the German invasion remained long unconfirmed, but his death has now been presumed. He will be remembered as a man of varied ability, strong character and personal charm, and it is to be hoped that he may have left further memorial of his devoted study of Cretan antiquity.

John L. Myres.

We regret to announce the following deaths:

Prof. A. C. Davis, jun., head of the Department of Experimental Engineering at Sibley College, Cornell University, on March 17, aged fifty-two.

Prof. W. E. Davis, professor of plant physiology at the Kansas State College of Agriculture and Applied Science, on January 17, aged seventy-five.

Prof. R. W. Hegner, professor of protozoology in Johns Hopkins University, on March 11, aged sixty-two.

NEWS and VIEWS

King's Birthday Honours List

The following names of scientific men and others associated with scientific work appear in the King's Birthday Honours list:

O.M.: Prof. E. D. Adrian, professor of physiology in the University of Cambridge.

Baron: Mr. J. M. Keynes, the distinguished economist.

K.C.M.G.: Sir Guy Marshall, director of the Imperial Institute of Entomology.

K.B.E.: Dr. C. G. Darwin, director of the National Physical Laboratory.

Knights: Prof. R. H. Fowler, Plummer professor of mathematical physics in the University of Cambridge, lately liaison officer in North America; Dr. W. H. Fyfe, principal and vice-chancellor of the University of Aberdeen; Mr. H. Gaskell, a director of Imperial Chemical Industries, Ltd.; Mr. W. Gavin, chief agricultural adviser, Ministry of Agriculture; Mr. L. Mason, deputy director-general of supply, India, and lately inspector-general of forests; Prof. W. F. Shaw, president of the Royal College of Obstetricians and Gynæcologists; Major-General J. Taylor, I.M.S., director of the Central Research Institute, Kasauli; Mr. R. A. Watson Watt, scientific adviser on telecommunications, Ministry of Aircraft Production.

C.B.: Dr. H. J. Gough, deputy controller-general of research and development, Ministry of Supply.

C.M.G.: Prof. D. B. Blacklock, professor of tropical hygiene, University of Liverpool; Mr. G. F. Clay, director of agriculture, Uganda; Dr. A. F. Mahaffy, director of the Yellow Fever Research Institute, Uganda.

C.I.E.: Mr. W. T. Hall, chief conservator of forests, United Provinces; Mr. C. M. Harlow, chief conservator of forests, Central Provinces and Berar; Colonel E. A. Glennie, director of the Survey of India; Lieut.-Colonel G. R. McRobert, professor of medicine, Medical College, Madras; Dr. L. E. Napier, director of the School of Tropical Medicine, Calcutta; Lieut.-Colonel E. McK. Taylor, director of the Irrigation Research Institute, Punjab.

C.B.E.: Mr. G. E. Bodkin, director of agriculture and principal of the College of Agriculture, Mauritius; Dr. E. A. Carmichael, director of the Neurological Research Unit of the Medical Research Council, National Hospital for Nervous Diseases; Prof. T. J. Mackie, professor of bacteriology, University of Edinburgh; Mr. F. J. Mortimer, lately president of the Royal Photographic Society; Prof. A. C. Norman, director of the X-Ray Institute in Iraq and professor of radiology in the Royal College of Medicine, Baghdad; Dr. Z. F. Willis, general secretary of the Y.M.C.A.

O.B.E.: Mr. V. A. Beckley, senior agricultural chemist, Kenya; Mr. E. G. Bowen, senior scientific officer, Ministry of Aircraft Production; Dr. H. J. O'D. Burk-Gaffney, senior pathologist, Tanganyika; Mr. S. Butterworth, principal scientific officer, Admiralty; Mr. T. G. Henderson, principal veterinary officer, Basutoland; Mr. G. D. A. Macdougall, chief assistant, Statistical Branch, Prime Minister's Office; Mr. A. Monro, chief veterinary officer, Ministry of Agriculture; Dr. B. Prasad, director of the Zoological Survey of India; Mr. A. H. Stein, divisional forest officer, Hoshangabad, India; Mr. C. B. Symes, medical entomologist, Kenya; Mr. A. F. Thelwell, secretary of the Jamaica Agricultural Society; Mr. A. F. Wilkins, principal scientific officer, Ministry of Aircraft Production; Mr. H. Wooldridge, senior scientific officer, Department of Scientific and Industrial Research.

M.B.E.: Canon L. A. Lennon, for services to education and agriculture, in Nigeria; Mr. G. W. Lines, agricultural officer, Nigeria; Mr. R. E. Mills, technical assistant, Ministry of Aircraft Production; Mr. H. C. Mundell, agricultural and livestock officer, Basutoland; Miss K. M. Shaw, personal assistant to the Dean, London School of Hygiene and Tropical Medicine; Mr. L. B. Turner, deputy assistant director, Explosives Department, Ministry of Supply; Mr. J. J. Unwin, scientific officer, Ministry of Aircraft Production.

I.S.O.: Mr. G. D. Goode, chief clerk, Department of Science and Agriculture, and personal secretary to the Director of Agriculture, Jamaica.

Prof. E. D. Adrian, O.M., F.R.S.

The recognition of the value of the work of Prof. E. D. Adrian to science by the award of the Order of Merit will be a source of great pleasure to his colleagues and students throughout the world. The advance in our knowledge of the working of the nervous system that has taken place in the last twenty years owes much to his long series of researches into the nature of the fundamental processes in nerve cells. As research in clinical neurology is able to make full use of this knowledge, further advances may also spring from his work, but this application must, of necessity, take a long time to reach fruition. Prof. Adrian's work on nerve and muscle, in association with Keith Lucas, started before the War of 1914–18; during that War he worked in clinical neurology, which gave him a wide experience and interest in neurology as well as electrophysiology. During the War of 1914–18 Keith Lucas and Adrian had discussed the new possibilities opened up by the thermionic valve, of investigating the electrical activity of the nervous system in detail. After Lucas's death, Adrian succeeded in realizing these possibilities, and in 1924 started the series of researches on the activity of single nerve fibres which in the next ten years were to yield such a rich harvest of new knowledge of the action of the sense organs and of reflex activity. As technical advances became possible these were adopted to refine the method, and his laboratory became the centre of research in electrophysiology to which research workers went from all over the world to learn these methods. The focus of work gradually moved from the investigation of the electrical activity of peripheral nerve fibres to that of nerve cells and synaptic regions of the central nervous system.

The spread of interest in brain potentials in man is largely due to Adrian's work in this field; the implications of the discoveries in this field by Hans Berger were not generally realized and the discoveries lay dormant for ten years until Adrian reinvestigated them, confirmed and extended Berger's work, and linked up his findings with general knowledge of the nervous system by animal experiments. Adrian's main interest has always been to discover the principles underlying all nervous structures as these apply throughout the animal kingdom, and the application of these to the nervous system of man. Thus his work on the electrical activity of the nerve ganglion of the water beetle assisted him in interpreting brain potentials in man; again, experiments on single motor nerve fibres in cats led to the investigation of voluntary control of human muscles in intact man by needle electrodes, and this method has become a valuable tool to the neurologist in investigating the nature of nervous diseases. Adrian's work owes much to his manual dexterity; he carries out all details of experiments himself and constructs much of his own apparatus. He encourages his students to work in the same way to the surprise of some visitors who expect to find a large staff of technical assistants. The success of this policy of close contact with experimental material is attested by the large volume of research carried out by students in his laboratory, and by schools founded abroad by physiologists trained in electrophysiological research in Cambridge. Since Prof. Adrian's work on individual nerve cells has been complementary to the researches of the Sherrington School on reflex action and the behaviour of large numbers of neurones, it is fitting that he should join Sir Charles Sherrington in the select company of those who have received the Order of Merit.

Science and Engineering in China

IN a review of developments in China under the republican regime entitled "China To-day: The Thirtieth Anniversary of the Chinese Republic, 1911–1941" (Central Union of Chinese Students in Great Britain and Northern Ireland, Sidney Sussex College, Cambridge. Pp. 55. 1*s*.) there are three articles of special interest to scientific workers. The first of these, by P. M. Yap, describes the utilization of science in China, where science and statecraft are already closely linked. In peace-time, the National Economic Council is responsible for economic planning, the execution of its plans resting with the Ministries of Economic Affairs, Agriculture and Forestry, and Communications. The former maintains three research institutes for hydraulic engineering, for mining and metallurgy, and for industrial technology. Under the Ministry of Agriculture there is the National Agricultural Research Institute, and various research bureaux are attached to the Ministry of Communications, and also directly to the National Economic Council. The National Health Administration has steadily established a series of public health stations and clinics all over the country and has contributed much to the expansion and improvement of the Army Medical Service. Most of its research and development work is carried out in the National Institute of Health. Apart from the universities and private research foundations, scientific research of the long-range type is carried out by the Academia Sinica and the National Academy at Peiping, the former of which, through the National Research Council, is responsible for directing and co-ordinating scientific activities in China.

The difficulties which face the development of the medical profession in China are outlined in an article "Unburied Ghosts", which indicates that traditional knowledge and forms of medical practice are likely to be detrimental to the progress of medical science, particularly in view of the low proportion of medical students with a scientific outlook. A brighter picture is given by T. C. Chan in his article "Review of Chinese Engineering". Despite the persistent opposition of Japan, particularly her destruction of Chinese engineering institutes by air attack, a vigorous engineering policy has been executed. During the second stage of the War, 386 factories were transplanted into the interior, while a further 1,378 factories have been recently established in eleven industrial centres all over free China, to increase production for military and non-military needs. At the end of 1940, the number of higher educational institutions, including universities and technical colleges, was 113, as against 108 before the War. Engineering works for communication and transport have been in full swing since 1937, and once peace is restored Mr. Chan considers that the effective development of Chinese industries will open up a new era for the engineering world.

The Royal Institution

THE managers of the Royal Institution have made special arrangements for carrying on the work of the Institution under the present conditions. Activities are necessarily somewhat limited by war circumstances, and many members of the staff of the Institution itself and of the Davy Faraday Research Laboratory are absent on war service. The laboratories and workshops are, however, fully employed, and a programme of lectures has been successfully carried out during the 1941–42 season. The Institution has also, with the managers' permission, been the centre for various scientific meetings and conferences in connexion with war purposes; among them, a course of special lectures, in November and December 1939, to meet the needs of students wishing to qualify for radio branches of the Defence Forces; a series of lectures on "The Nation's Larder", in April and May 1940, arranged with the approval and support of the Ministry of Food; and in September 1941, the Conference on Science and World Order, held by the Division for the Social and International Relations of Science of the British Association. It is hoped to maintain and perhaps extend the activities.

As a temporary measure, pending the appointment of a successor to Sir William Bragg, the managers have made the following appointments: The general secretary, Mr. Thomas Martin, on leave of absence with the Ministry of Supply, to be 'resident' in charge of the house; Mr. R. Cory, librarian, to be deputy general secretary; Dr. A. Muller, assistant director of the Davy Faraday Research Laboratory, to be acting director.

American Philosophical Society Research Grants

THE Yearbook of the American Philosophical Society, 1940, covers the year January 1–December 31, 1940, and in addition to the minutes of the executive sessions includes the reports of standing committees as well as of the Special Committee on Education and Participation in Science, the purposes of which are to conduct a survey of amateur science in the Philadelphia area and to stimulate participation of laymen in scientific research. Almost half the volume is occupied by the report of the Standing Committee on Research, which includes reports from recipients of grants from the Penrose Fund, from which 107 grants, totalling some 360,750 dollars, were awarded during the year. Of these, two were in mathematics, five in astronomy and astrophysics, seven in physics and eleven in chemistry and geochemistry. Eight grants were made in zoology, four in genetics and cytology, nine in botany, eight in physiology, one in biochemistry, four in pathology and medicine, ten in American and modern history, one in political science, four in archæology, and four in ethnology. The distribution is roughly proportional to the number of applications from the different classes, and the Committee on Research has always attempted to make the grants to the most worthy applicants without reference to the subjects represented. Further, since the funds at the disposal of the Committee are insufficient to make long-continuing grants, the policy has been to help start or finish worthy projects rather than to furnish continuing support, nor have grants been made to pay in whole or part the salaries of members of the staff of any institution, nor in general to pay living expenses of applicants.

New Exchange-Area Cable

AN article by N. V. Firth (*Bell Lab. Rec.*, 20, No. 8; April, 1942) describes an investigation carried out to determine whether the most economical series of new telephone cables would result from reductions in the diameters of cables having 24- and 26-gauge conductors, together with the addition of a cable with conductors of a smaller size such as 28-gauge, or whether the 24- and 26-gauge should be superseded by 25- and 27-gauge. Experimental lengths of cable were manufactured with conductors of each of these sizes, all with reduced amounts of pulp insulation. Studies of dielectric strength were made on each type. Thickness of pulp insulations used for full-sized cables containing 1,515 pairs of 24-gauge, 1,818 pairs of 25-gauge, 2,121 pairs of 26-gauge, 2,424 pairs of 27-gauge, or 3,030 pairs of 28-gauge provide satisfactory dielectric strength. No major alterations in the cable manufacturing equipment would be required for the introduction of any of these new types. A study of overall savings indicated that the greatest advantage would result by retaining the four existing standard gauge sizes and increasing the maximum number of pairs in 24-gauge and 26-gauge cables to 1,515 and 2,121 pairs respectively. Thinner insulations of the new cables have somewhat lower dielectric strengths than those of the previously standard 24- and 26-gauge pulp-insulated cables. Tests indicate, however, that they are at least as good as the corresponding strip-insulated 24- and 26-gauge cables which form a large part of the existing plant.

For assembling the required number of 24- or 26-gauge pairs into cables the method is the same as that for the previously standard 24- or 26-gauge designs. Cables ranging in sizes from 11 pairs to 101 pairs are stranded as a single unit. Those larger than 101 pairs and up to 303 pairs are first built up in small units of 50 or 51 pairs which are then assembled in long spirals to form the completed cable. All sizes larger than 303 pairs are formed similarly from units of 101 pairs each. The colour code for the groupings of pairs remains the same in the new designs as in other unit type cable in recent years. The larger number of pairs obtainable in the full sizes of these new designs will in some instances prove economical in plant rearrangements incident to central-office cutovers and should be advantageous in making additions to plant where there is underground conduit congestion. The major savings, however, are expected from the reductions in sheath diameters for cables of the same numbers of pairs as formerly.

Earthquake Recorded at Kew

THE strong earthquake of May 14 in Ecuador (NATURE, May 23, p. 578, and May 30, p. 607) was recorded at Kew Observatory, *iP* appearing on all components of the seismograph at 02h. 25m. 51s. U.T. This was compressional. A full suite of pulses followed and the shock finished recording at about 07h. 45m. U.T. The estimated epicentral distance was 9,520 km. All interpretations are tentative.

Announcements

MR. WILLIAM MORRISH SELVEY is to continue for another year as president of the Institute of Fuel. Mr. Selvey, who has been connected with the Institute since its inception, and has for several years been chairman of the Council, took office as president in October 1941.

THE following appointments and promotions in the Colonial Service have recently been made: H. D. Jordan, agricultural officer, Sierra Leone; A. G. Beattie (assistant director of agriculture), deputy director of agriculture, Nigeria; L. D. Cleare (entomologist), deputy director of agriculture, British Guiana; R. M. Davies (senior agricultural officer, Tanganyika Territory), senior agricultural officer, Zanzibar; I. E. James (principal agricultural officer), assistant director of agriculture, Nigeria; D. H. Urquhart (senior agricultural officer), principal agricultural officer, Nigeria.

MR. T. SHEPPARD has produced an important catalogue of the Bronze Age implements in the Mortimer Museum, Hull (*Hull Museum Pub.*, No. 213). There are a number of illustrations. Hull has been fortunate in the past in the matter of acquisitions and its Bronze Age collections are important. Prehistorians, therefore, will be grateful for this new catalogue.

LETTERS TO THE EDITORS

The Editors do not hold themselves responsible for opinions expressed by their correspondents. No notice is taken of anonymous communications.

Origin of the Solar System

THE tidal theory of the origin of the solar system which I proposed in 1916 supposed that when the planets were born, the sun was comparable in size with the present planetary orbits. Recent workers at the subject have, however, supposed that the sun was of about its present size.

Yet on any reasonable view of stellar evolution, there must have been a time in the past when the sun, then rapidly contracting, extended to thousands of times its present radius. If, for simplicity, we imagine an epoch in which sun and stars all had precisely n times their present radii, the chance (per unit time) of planets being generated by a tidal encounter of the type contemplated by my theory would be n^2 times as great as now. For example, when the sun extended as a semi-nebulous mass to the orbit of Uranus, the chances would be 17,000,000 times as great as now: more planetary systems would be born in 120 years then than in 2,000 million years of present conditions.

Let A denote the chance (per unit time) of planets being born out of our sun under present conditions, this being of the order of $(5 \times 10^{18}\ \text{years})^{-1}$. Then the total chance of planets having been born in the whole period since the sun was of N times its present radius is

$$A \int n^2\,dt = -A \int_1^N \frac{n^2\,dn}{dn/dt}.$$

In its earliest stages, in which n was large, the sun was probably engaged in a rapid Helmholtz contraction, having no sources of energy beyond its own gravitation. Assuming Lane's law to hold, the rate of solar radiation would be C/n^2, where C is the present rate, and the exhaustion of the sun's energy would be G/n, where G is the present exhaustion. Equating C/n^2 to the rate of increase of G/n, we find that $-dn/dt$ has the constant value C/G. This is about $(2 \times 10^7\ \text{years})^{-1}$, since G/C is the time through which the sun could have radiated at its present rate on the Helmholtz theory of gravitational contraction, that is, Kelvin's estimate of the maximum age of the earth.

If we replace $-dn/dt$ by C/G, the above integral assumes the value $\frac{AG}{3C} N^3$, or about $10^{-12}N^3$. The true value must be greater than this, since every additional source of energy retards contraction, and so decreases the value of $-dn/dt$. But it will not be much greater, since nearly all the value of the integral comes from large values of n, for which our approximation is good; the contribution from values of n near to unity, where our approximation fails through other sources of energy being operative, is quite insignificant.

If we take N equal to 5,000, we start from a sun which is big enough to include the orbit of Uranus, and yet is not too diffuse to hang together dynamically, and find that the planets are most likely to have been formed before n fell much below 4,000. With such values for n, we escape the very serious dynamical difficulties which result from supposing that the sun was of its present size when the planets were born. Moreover, the integral gives the total chance of planets being born as 1 in 6, whereas the chance of a sun of the present size producing planets in 2,000 million years is only about 1 in 2,500,000,000. Thus there is no longer any need to strain the probabilities to account for the existence of the planets.

The average mass of planets born by gravitational instability out of a gaseous filament varies as $T^{\frac{3}{2}}\rho^{-\frac{1}{2}}$ and if we again assume Lane's law this remains constant through the contraction. The minimum mass which can hold together gravitationally, without scattering into space, also varies as $T^{\frac{3}{2}}\rho^{-\frac{1}{2}}$, so that this again remains constant. Thus the values of these two quantities will not be affected by an increase in the value of n.

The foregoing rough calculations obviously call for many adjustments: for example, Lane's law cannot be expected to give accurate results for a star of 5,000 times the diameter of the sun. But most of the adjustments will, I think, be found to strengthen, rather than weaken, the case I have been putting and, even if some do not, there is an ample margin to spare. Thus I suggest, although very tentatively, that:

(1) Of the various planetary systems in the sky, the vast majority were formed while their suns were still in a semi-nebulous state.

(2) The supposition that our own system was formed while the sun was still a semi-nebulous mass, of hundreds or perhaps thousands of times its present diameter, avoids most—perhaps all—of the dynamical objections which have recently been urged against the tidal theory.

(3) A far larger proportion of the stars than we have hitherto imagined must be accompanied by planets; life may be incomparably more abundant in the universe than we have thought.

J. H. JEANS.

The Amphibian Pituitary

IN a recent paper[1] Atwell reports an examination of the pituitary complex of *Xenopus lævis*, and concludes the discussion with the assertion that this species "does not afford unique morphological opportunities for determining the function of the *pars tuberalis*". So stated, this controverts earlier views expressed by Hogben and Slome[2,3]; but a lengthy addendum printed after it shows that Atwell's findings are not necessarily in opposition to views expressed by workers in my laboratory. What difference of opinion exists seems to be a semantic rather than a factual issue. There is no disagreement concerning the following facts:

(*a*) The anterior lobe of Xenopus has a prominent median 'anterior process' made up of basophil cells.

(*b*) The pituitary of Rana has no such process; but a corresponding vestigial structure may be present in toads (Arcifera).

(*c*) The pars tuberalis of Bufo is represented by a pair of glandular discs lying on the infundibulum, detached in the process of development from the two extremities of a bifid outgrowth in much the same position as the anterior process of Xenopus.

Atwell now contributes the additional information that there are comparable discs on the infundibulum of Xenopus but concedes: (*a*) they are "composed of small cells which give slight indication of glandular capacities"; (*b*) "it is not surprising that (*they*) have been overlooked by other observers". It is not clear what the epithet "slight" signifies in this context. From my own experience at the time when I first examined the pituitary of Xenopus I can confirm the existence of these discs; and am not disposed to dispute their *structural* homology with the paired glandular lobes of Firmisternia. I rejected, and still reject, the propriety of regarding them as *functionally* equivalent to the latter because indications of their glandular activity are at most as slight as stated above.

If they are not functionally active, the validity of the view under discussion turns on whether the anterior process of Xenopus corresponds to the base of the embryonic tuberalis of other Anura at the time of metamorphosis. In the text which precedes the postscript mentioned, Atwell casts doubt on this. He states: "whether the anterior process represents the region of earlier attachment of the pars tuberalis, and whether it is histologically related to the pars tuberalis are unknown". The addendum which follows the discussion deals with the development of the pituitary complex of *Bufo boreas boreas*, a species with a detached anterior process of variable size. Atwell there describes its origin as follows: "The lateral lobes which are destined to form the pars tuberalis are still attached to the anterior lobe by a single median stalk . . . there is a constriction between the anterior lobe and the single stem of the Y. . . . If this constricting process should continue to the point of complete separation and the lateral lobes should become detached (as apparently they always do) to form the two plates of the pars tuberalis, then this central mass of cells would be left isolated on the surface of the median eminence. . . . It seems justifiable to conclude that the anterior process of the hypophysis of *B. boreas boreas* is a rudimentary structure probably derived from the median stalk which served to attach the embryonic pars tuberalis to the anterior lobe."

My original reason (see ref. 3, p. 168) for regarding the anterior process of Xenopus as the functional equivalent of the paired pars tuberalis of other Anura was based on Atwell's earlier description of the development of *Bufo americana*[4]. This species also has a *Y*-shaped extension at the time of metamorphosis. Atwell now appears to agree: (*a*) that the anterior process of Xenopus is equivalent to the anterior process of *B. boreas boreas*; (*b*) that the anterior process of the latter is the persistent median portion of the *Y*-shaped extension of the embryonic pars anterior. Thus the only matter about which there is difference of opinion is whether we are entitled to apply the term pars tuberalis: (*a*) to derivatives of the *whole* embryonic structure including the persistent median portion which apparently persists as a prominent glandular lobe in Xenopus and disappears in Rana; (*b*) *only* to the remains of the lateral limbs which persist in all Anura but merely as vestigial organs in Xenopus. I am still inclined to regard the former as more reasonable. Either way, the pituitary of Xenopus offers unique opportunities for studying the physiological properties of histologically differentiated components of the pituitary complex.

Microbiological Assay of Riboflavin in Cereals

THE assay of riboflavin in cereals by fluorometric methods[1,2] is difficult and the results are of doubtful reliability. One difficulty is the low riboflavin content of cereals. There is also the possibility of the presence of interfering substances in cereal extracts. On the other hand, the microbiological method of Snell and Strong[3], using *Lactobacillus helveticus*, with certain modifications, has proved to be satisfactory and expeditious.

The work described below will be published later in detail, but the chief modifications that have been introduced are the addition of xylose, asparagine, nicotinic and pantothenic acids to Snell and Strong's original medium, and the method of preparing the extract. The actual estimation was carried out by measuring the turbidity of the solutions nephelometrically or by titrating the amount of lactic acid formed by the bacteria with 0·1 *N* NaOH. The results from either of these methods of estimation are in good agreement.

It has been shown[4] that starch has a marked effect in stimulating the growth of *L. helveticus*, and as cereals contain a large amount of starch, this must be destroyed in the extract before the estimation is carried out. Scott *et al.* recommend taka-diastase for this purpose. In the present investigation it was found, however, that taka-diastase was unsatisfactory. The various samples of the enzyme used showed a marked stimulating activity over other hydrolysing agents, such as ptyalin, sulphuric and hydrochloric acid. The method of extraction that was eventually adopted was to hydrolyse suitable weighed samples of material with 0·25*N* HCl for 15 minutes at 15 lb. pressure in an autoclave. Nevertheless, hydrolysis with ptyalin in place of taka-diastase[4] or refluxing for one hour with 0·25*N* sulphuric acid[1] or 0·25*N* hydrochloric acid were all found to give the same results as autoclaving for 15 minutes. Autoclaving of the material was adopted simply because it was found to be more convenient.

Results from the different methods of extraction are given below:

	Sample	Riboflavin content γ/gm.
	National straight run flour (75 per cent extraction)	
1.	Hydrolysed with ptyalin	0·75
2.	Refluxed with 0·25*N* H_2SO_4 for 1 hour	0·75
3.	,, ,, ,, HCl ,, ,, ,,	0·8
4.	Autoclaved at 15 lb. pressure for 15 min. with 0·25*N* HCl	0·8
5.	Hydrolysed with taka-diastase	1·15

The results of a number of determinations on different varieties of wheat, various fractions of the wheat grain, wheaten flours, as well as other cereals are given in the accompanying table: figures are

	Sample	Riboflavin content γ/gm.
1.	Wheat, English	2·65
2.	,, Manitoba	2·9
3.	,, Australian	2·65
4.	,, Russian	3·7
5.	,, Testa	5·8
6.	,, Aleurone layer	6·3
7.	,, Germ, commercial sample (1)	11·35
8.	,, ,, ,, ,, (2)	12·85
9.	,, ,, ,, ,, (3)	9·7
10.	Flour A roll	0·4–0·5
11.	,, C ,,	0·5–0·6
12.	,, National straight run (75 per cent extraction)	0·75–1·25
13.	,, National wheatmeal (85 per cent extraction)	2·0–2·1
14.	Barley	2·3
15.	Rye	2·65

based on the normal water contents of the products.

Since this work was completed, Andrews, Boyd and Terry[5] have published results for the riboflavin content of different cereals, using apparently the original Snell and Strong procedure, but no details of the medium are given. With the exception of patent flour, their results are all much lower than those now reported. One explanation for these low figures is that their extracts were too concentrated (5–10 gm. made up to 100 ml.). In my experience there is always a falling off in estimated riboflavin content if the extract is too concentrated. The extracts used in the present investigation were always made up to 500 ml., and in some cases, for example, germ, to 1,000 ml.

It is of interest to note that Miss Copping[6] (see also in this connexion Bacharach[7]), using a biological method, obtained values of the order of 2–3 γ per gram for a National wheatmeal, or of the same order as those reported here. A further proof that the microbiological method is specific is shown by the fact that for milk the values obtained by me (1·4–1·5 γ/ml.) are practically identical with those obtained by the fluorometric method[7].

Disappearance of the Ascorbic Acid in Raw Cabbage after Mincing or Chopping

Pyke[1] has lately stated that when raw savoy cabbage was shredded by means of household shredders part of the ascorbic acid disappeared during the ensuing 5–10 minutes and thereafter no further loss occurred during three hours standing; the extent of the initial loss of ascorbic acid varied with the type of shredder used. His explanation is that the initial loss of ascorbic acid is essentially due to the mechanical rupture of the cells, and will therefore vary with differing types of shredder or grinder.

As mentioned previously[2], we have been working on similar lines and have sought to find a correlation between mechanical breakage of cells and loss of ascorbic acid. It would appear that the amount of liquid which can be squeezed from shredded cabbage would be indicative of the breakdown of cell tissue, and we have proceeded on this line of attack. *Inter alia* we have confirmed Pyke's results.

In Fig. 1 the concentration of ascorbic acid in minced cabbage, expressed as a percentage of that originally present, is plotted against the time of standing after mincing. The curves show that the concentration of ascorbic acid falls rapidly during the first 10–15 minutes. The steady value reached remains constant for periods up to thirty hours (provided that the cabbage be kept cool, at, say, 15° C.). The extent of the initial loss of ascorbic acid varies with the type of mincer used.

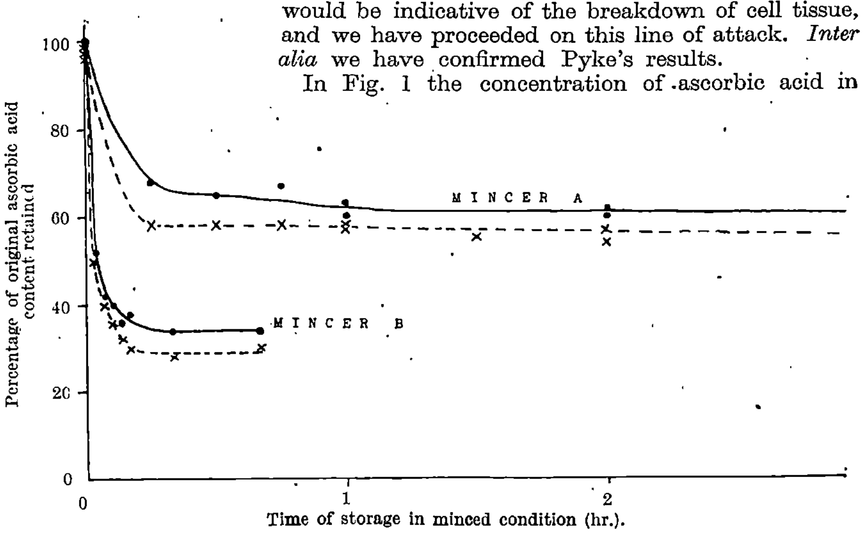

Fig. 1.

●——● total ascorbic acid; x – – – – – x, reduced ascorbic acid.

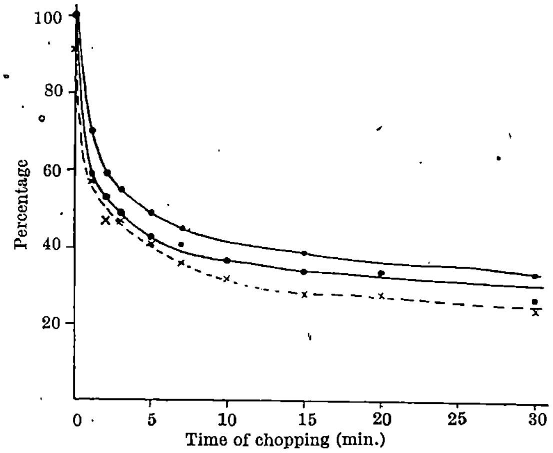

Fig. 2.

●——●, total ascorbic acid. x – – – – x, reduced ascorbic acid.

Uppermost curve, percentage of residue from pressing; other two curves, percentage of original ascorbic acid retained.

All samples allowed to stand for 2 hr. after chopping.

Some confirmation of the theory that the extent of initial loss varies with the extent of rupture of cells has been obtained by chopping cabbage in a machine primarily used for chopping sausage mixes. The material to be chopped is placed in a bowl which revolves beneath a set of rotating knives; for short periods of chopping the degree of comminution obtained is considered to be roughly proportional to the time of chopping. Samples were withdrawn at intervals and allowed to stand. The concentration of ascorbic acid was determined in these samples after two hours, when a steady state had been reached, and again after twenty-two hours. At the same time the amount of juice which could be pressed from each sample under certain conditions was determined. The results are plotted in Figs. 2 and 3 and indicate that the longer the time of chopping the greater the percentage of ascorbic acid lost and the greater the amount of juice which may be obtained by pressing. In Fig. 2 the correspondence between the curves for the percentage of ascorbic acid lost and the percentage of residual material after pressing may be fortuitous.

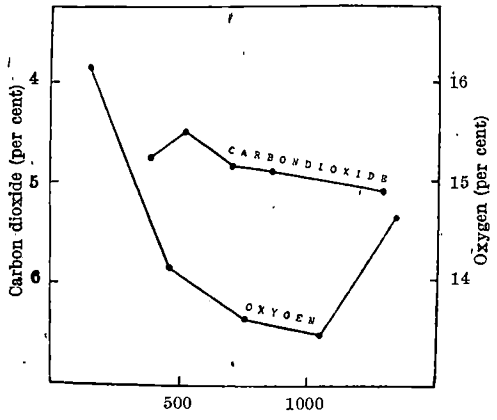
The 'Oxygen Trough' of Expiration

I have been unable to confirm[1] the presence of an alveolar air plateau as described by Haldane[2]. Two of the subjects investigated gave paradoxical results in that the ultimate alveolar sample had a lower carbon dioxide tension than the penultimate. In a paper presented at the same time, Cotton[3] examined the oxygen percentages, and demonstrated what he later described as the "oxygen trough of expiration". His oxygen figures were in harmony with my results; that is, the percentage of oxygen of the ultimate sample was higher than that of the penultimate.



The oxygen results from one of the subjects used by me are given in the accompanying graph. They confirm the findings of Cotton.

No satisfactory explanation of this phenomenon, which has recently been confirmed by Marenzi and Costoya[4], is at present available. It seems reasonable to assume that it is due to inequality of ventilation, or inequality of the blood-flow to the different parts of the lung.

Crystal Dynamics of Rocksalt

THE early X-ray experiments of James, Firth and Waller[1] on the modification of the diffracting power of crystals of sodium chloride due to thermal vibrations of the atoms dealt only with the reduction in intensity of the Bragg reflexions at different temperatures, and could therefore only give average root mean square amplitudes, but the more recent diffuse spot methods promise to give information concerning the whole frequency spectrum. By observation of the position, shape and intensity of the diffuse spots when the crystal is turned into a succession of reflecting positions, the effect of vibrations travelling in different directions, polarized in definite ways and with frequencies within known limits, can be traced[2,3,4].

The above interpretation of the diffuse spot photographs has, however, been challenged by Sir C. V. Raman[5], and one of his colleagues, Dr. C. S. Venkateswaran[6], has published experimental results for sodium chloride crystals which are claimed to be inconsistent with the thermal (Faxén-Waller) theory. Since the challenge includes a denial of the validity of the Born theory of lattice dynamics, it is important that the experimental evidence should be carefully examined.

Venkateswaran's observations are as follows: (1) variation of diffuse spot intensity with temperature (one crystal setting, three temperatures); (2) comparison of diffuse spot and Laue spot intensities for three different irradiated volumes of crystal, using a slightly divergent beam; (3) measurements of relative sharpness; and (4) intensity, of 200, 400, 600 reflexions (molybdenum unfiltered radiation, one crystal setting); (5) comparison of 111, 222 reflexions; (6) measurement of the 'drift' of the diffuse maxima towards the Laue spots as the crystal rotates.

Every one of these experimental observations is either inaccurately performed or wrongly interpreted. The main criticisms are as follows:

(1) Venkateswaran has neglected the falling off of

atomic scattering power with temperature, an important effect which would reduce his deduced 'X-ray active' frequency from 160 cm.$^{-1}$ (his figure) to 100 cm.$^{-1}$. The latter does not correspond to a Raman frequency, and is in fact altogether below the range of optical frequencies for NaCl. It corresponds to an angular frequency $1{\cdot}89 \times 10^{13}$, but no reliance can be placed even upon this figure (although it would agree well with the thermal theory), since the intensity measurements are obviously extremely rough and limited in extent.

(2) He assumes that Laue spot and thermal spot intensities should vary differently with crystal volume. This is not the case; both are proportional to the crystal volume, proper experimental precautions being taken and corrections made[7]. Venkateswaran has compared diffuse spots given by $\lambda = 0{\cdot}710$ with Laue spots due to $\lambda = 0{\cdot}417$, $0{\cdot}592$ and $0{\cdot}401$ A., using a thick crystal for which no differential absorption corrections are made. He states that there is no variation of the Laue/diffuse spot intensities, as indeed the thermal theory predicts, but his photographs cannot be accepted as serious evidence either way.

(3) He assumes that the velocities of elastic vibrations are identical in all directions and irrespective of polarization (Raman also states that such a simplified treatment "should be a fair approximation to the truth"; *ibid.*, p. 344). A recognition that this is far from being true is vital to a proper comparison of theory and experiment. Venkateswaran's measurements of sharpness, etc., are in reasonable agreement with the correct version of the thermal theory, though not with the approximate theory that he assumes.

(4) His assumption that the thermal theory predicts the same law of intensity decay with angle of diffraction for diffuse as for Bragg reflexions is incorrect. Temporary displacements of atoms naturally affect the small-spacing and high-order reflexions much more than those of large spacing or low order. This was well confirmed by Laval's careful observations[8]. He found for potassium chloride at 290° C., using molybdenum $K\alpha$ monochromatized radiation and measuring the diffuse spot intensities (by the ionization spectrometer) at a constant angular displacement from the Bragg reflecting positions:

	002	004	006	008	0010
Bragg intensity	100	20	7	3	1
Diffuse intensity	100	50	33	21	12

For planes of similar structure factor but different force constants the diffuse spot intensities may bear little relationship to the Bragg intensities. This was also confirmed by Laval.

(5) It follows from (4) that Venkateswaran was wrong in expecting that, according to the thermal theory, the 111 : 222 diffuse spot intensity ratio would be equal to that of the Bragg spots. Moreover, the method he used of obtaining the diffuse reflexions by transmission through a thick crystal of an "effective X-ray wave-length maximum" of 0·46 A. was quite unsuitable for comparison of intensities. In fact, Fig. 3 (plate 29) of his paper shows that some molybdenum characteristic radiation was also being transmitted, and this would certainly invalidate his measurements. Accurate intensity comparisons are only possible using monochromatic radiation, proper allowance being made for 'unwanted' components.

(6) In order to explain the drift of the diffuse maxima towards the Laue spots, Venkateswaran postulates 'phase-waves' parallel to certain of the {311} planes. This drift is a natural consequence of the thermal theory, which predicts its magnitude and direction correctly[9] and without any extraneous assumptions.

I do not suggest that the thermal theory has reached a state of perfection and is now beyond criticism. That is not the case. It may, however, be claimed that the experiments described by Venkateswaran, in so far as the results are of value, confirm and do not contradict the thermal theory. From this point of view, therefore, there is no ground for criticism of the Born lattice theory.

Regulation of Experiments on Living Animals

At the end of June a somewhat rare event will take place. The Home Office will make an appointment under the Cruelty to Animals Act, 1876, which regulates the practice of experiments on living animals.

An inspector under the Act exercises an important function, not, indeed, as a policeman, but in advising research workers as to the interpretation of their obligations in particular cases. In view of the number of experiments licensed under the Act, direct supervision is not practicable on any material scale, but I assume that the majority of research workers do not desire to contravene the regulations, and that the inspector's guidance will in general be effective.

The Act lays down a compromise between the claims of science, on one hand, and the rights of animals, on the other; the line drawn in the practical application of the compromise must inevitably be an arbitrary one. Until somebody can lay down clear-cut rules which will command general assent, the best that can be done is to make as fair a compromise as possible. This calls for exceptional impartiality, and since a man with the indispensable scientific training will necessarily have a predisposition in favour of science, it is important that he shall also have an offsetting predisposition in favour of the other party in the compromise. This could be ensured by requiring candidates for the post to prove that they have in the past been effectively associated with some effort to better man's treatment of animals, wild or domestic. Preferably they should also have veterinary knowledge.

RESEARCH ITEMS

Fishes from the Philippines

Bulletin, **13**, 100, of the United States National Museum (1941), is the sixth volume of Henry W. Fowler's studies of the fishes collected by the United States Bureau of Fisheries steamer *Albatross* in the Philippines. This is mainly on the primitive fishes, following through the various groups of living forms to the more generalized bony types. The greater part deals with the sharks, rays and chimæras, but among the bony fishes clupeoids, catfishes and carp are included. It is a handsome volume of nearly nine hundred pages and will be of much use to systematists not only for the description of species but also for the analyses given of sub-classes, orders, families and genera which include general definitions. The type of each genus is noted but the species dealt with are only those occurring in the area studied. Most of the localities recorded relate to the Philippines, but other regions where the *Albatross* cruised, as the Netherland Indies, China, Formosa and parts of Oceania, are also listed. General and very brief notes on breeding and food in the various families are occasionally given. More of this would be welcome. The statement on p. 24 that all the Scyliorhinidæ, so far as is known, appear to be viviparous, is obviously a slip, as the egg cases and attachments to weeds and rocks are described.

Study of a Deepwater Fish

WILBERT MCLEOD CHAPMAN ("The Osteology and Relationships of the Bathypelagic Fish *Macropinna microstoma* with notes on its Visceral Anatomy", *Ann. and Mag. Nat. Hist.*, Eleventh Series, **9**, No. 52; 1942) has described previously the external anatomy of this fish (1939) and indicated its relationships with Opisthoproctus. He found, however, that there were sufficient differences from the latter to warrant the formation of a new family. A further specimen being available for anatomical study the skeleton was worked out in detail, also the gross visceral anatomy, and, to some extent, the musculature. Of particular interest are the great changes in the head region occasioned by the enormous dorsally directed eyes, the peculiarities of the oral regions, and the absence of an air bladder. The new family Macropinnidæ is proposed to include the genus Macropinna, while in the family Opisthoproctidæ the new genus Grimaldia is proposed for *Opisthoproctus grimaldi* Zugmayer. The relationships of other little-known genera are also discussed.

Accuracy of a Few Observations in a Large Population

W. L. STEVENS (*J. Genetics*, **43**, 301; 1942) points out that the customary attachment of an estimated standard error to indicate the limits of accuracy of a mean value may lead to misinterpretation in those cases where the distribution is not normal and the value is based on small numbers. Such a case is the estimate of a mutation-rate in a population N where the ratio n/N (n being the number of observed mutations) is very small. For example, the occurrence of three mutations in 1431 cultures gave a mutation rate of 0·21 per cent $\pm 0 \cdot 12$; thus a negative mutation rate would be perfectly reasonable with such a method of estimating the limits of accuracy. To overcome these difficulties, the author provides a useful table whereby the limits of accuracy of values based on less than fifteen individuals may be rapidly estimated. For genetical work and possibly in other directions this table will be of great service.

Cell Division in Small and Large Cells

E. W. SINNOTT (*Proc. Nat. Acad. Sci.*, **28**, 36; 1942) has shown that large and small cells divide and multiply at the same rate in the fruits of several cucurbits where cell division is in progress. Therefore he concludes that cell division is controlled by some factor, independent of cell size, throughout the different tissues of an organ.

Carbonization

EXPERIMENTS on the gaseous products of carbonization by heating of cellulose, glycine, petroleum coke, bakelite, anthracite and bituminous coal (K. Bolton, J. E. Cullingworth, B. P. Ghosh and J. W. Cobb, *J. Chem. Soc.*, 252; 1942) throw some interesting light on the mechanism of the process. Substances forming a solid residue form a repatterning of carbon atoms in a hexagonal network which resists any disintegrating tendency of further temperature rise and forms graphitic crystallites. It is established at 400°–500° and its progress is accompanied by a rise in density, rapid up to 800° (in coal, etc., such material is initially present). The other molecular groups form no part of this pattern or are easily detached from it, and are volatilized and expelled with rise of temperature. Some gaseous products (carbon dioxide and some carbon monoxide) appear early; the chief gaseous products (methane, hydrogen and carbon monoxide) come later and are regarded as formed from the more firmly attached CH_3, H and OH radicals by molecular condensations of the type: $R_1H + CH_3R_2 = R_1R_2 + CH_4$. The maximum emission of methane is at 500°–600°, the maximum hydrogen and carbon monoxide at 700°–800°. The latter is supposed to be formed from steam by a water gas reaction. The amounts of higher paraffins and unsaturated hydrocarbons are small with the substances tested.

Separation of Isotopes

THE separation of isotopes of oxygen and nitrogen by means of fractionating columns working with water and ammonia solutions has proved very successful. Some of these columns are very tall (60 ft. or more) and the question of packing becomes important, among other ways in that of expense. H. G. Thode and F. O. Walkling (*Can. J. Res.*, **20**, 61; 1942) have used a packing which is inert, cheap and easily wetted, which has given results and is suggested for use in industrial separation of isotopes. This was a shale which had been passed through a furnace at a temperature well above the melting point; the clinkers being crushed, cleaned and graded according to particle size. The fractionating column was tested with water and ammonia solution. In the second case a 60 per cent solution of ammonium nitrate is pumped to the top of a fractionating column at a constant rate, drains to the foot of the column where it reacts with alkali to liberate ammonia, which is stripped and returns to the column where it flows to the top against the current solution. Since ^{15}N is favoured in the liquid phase, there is a net transport of it towards the foot of the column, where it concentrates. The apparatus is worked at room temperature and 10 cm. pressure. Some figures for different types of packing are given.

Faxén-Waller Theory of Diffuse X-Ray Scattering

An elementary derivation of the Faxén-Waller formula for the diffuse scattering of X-rays by thermally excited lattice vibrations and the shapes of the surfaces of isodiffusion in reciprocal space for some cubic crystals has recently been given by H. A. Jahn (*Proc. Roy. Soc.*, A, 179, 320; 1942). It is shown that for substances with high elastic anisotropy large deviations from spherical character are to be expected for the surfaces of isodiffusion belonging to each of the individual lattice planes and, moreover, marked differences in shape between surfaces belonging to different lattice planes. The theory is illustrated by calculations made for a single crystal of sodium.

Magnetostriction

F. Brailsford and R. G. Martindale describe the results of an investigation into the magnetostriction of five grades of iron and silicon-iron electrical sheets, including a cold-rolled silicon steel and a high silicon steel (*J. Inst. Elec. Eng.*, 89, Pt. 1, No. 17, May, 1942). The silicon content varied from 0·14 per cent to 6·26 per cent. Measurements were made on strip specimens 24 in. long by 2 in. wide by 0·014–0·016 in. thick. A solenoid 20 in. long and 3 in. inside diameter was used to magnetize the strip, the magnetic circuit being completed by a massive laminated yoke. Measurements of magnetostriction were confined to a length of 5 in. at the centre of the specimen, and the variation of flux density over this length was less than 5 per cent. Changes in length were measured by a small extensometer specially developed for the purpose. Readings were made by a telescope and cross-wires on an illuminated scale, the magnification being rather more than 100,000. As the scale could be read to 0·01 in., a change in length of 10^{-7} in. could be detected. A typical maximum magnetostrictive strain of 4×10^{-6} could, therefore, be read to about ½ of 1 per cent. Magnetostriction in the sheet materials was found to vary considerably, depending upon the direction in the sheet relative to the rolling direction. The general form and direction of traversal of the hysteresis loops formed by plotting magnetostriction against flux density can also vary, depending upon the material and other factors. The theoretical analysis, while very approximate in its application to polycrystalline material, nevertheless gives some evidence for the view that, on account of the method of demagnetization or the presence of directional residual strains, the initial distribution of domains in the material in the demagnetized condition is not purely a random one. This in turn might be an important contributory factor to the magnetic anisotropy observed to occur at flux densities below the 'knee' of the magnetization curve. A number of graphs is given showing the variations of magnetostriction with changes of values of the different variables affecting the phenomenon.

mpulse Voltage Measurements

IN a paper read before the Institution of Electrical Engineers recently on measurements on impulse voltages with a ballistic galvanometer, G. W. Bowdler describes two simple circuits for measuring the crest value and duration of transient impulse-testing voltages. In the measurement of crest voltage, the impulse is applied to a resistor-divider, the voltage across a part of which is applied through a thermionic ectifier to a capacitor which is connected to the galvanometer through a series resistance. A bias battery suppresses any steady thermionic current tending to flow through the valve and galvanometer. For measuring time-lag, a fraction of the impulse voltage is applied to the grid of a triode from a resistor-divider. The galvanometer and anode battery are shunted by capacitors which have impedances negligible compared with that of the series resistance in the anode circuit. A series resistance in the galvanometer circuit isolates the galvanometer from the applied impulse voltage when measurements are being made on negative impulses. Both methods of measurement are compared with the results obtained simultaneously by a high-speed cathode ray oscillograph. The agreement in crest voltage was within 2 per cent even with voltages of the order of 10^{-7} sec. duration, and in time-lag the agreement was within 0·2 microsec. when the grid bias of the valve was suitably adjusted. The measurements are not critically dependent on the characteristics of the thermionic valves used in the circuit, and the range of voltages which may be measured can easily be extended by the use of suitable high-voltage resistors. The two circuits described have been assembled conveniently into a general impulse-measuring equipment with mains-operated supplies for the valves. As an example of its use, the time-lag curve of a 10-in. rod gap, obtained in a small fraction of the time necessary to do so by oscillographic methods, is reproduced. The paper concludes with a record of a few measurements made with this apparatus of the lengths of the front and tail of an impulse wave.

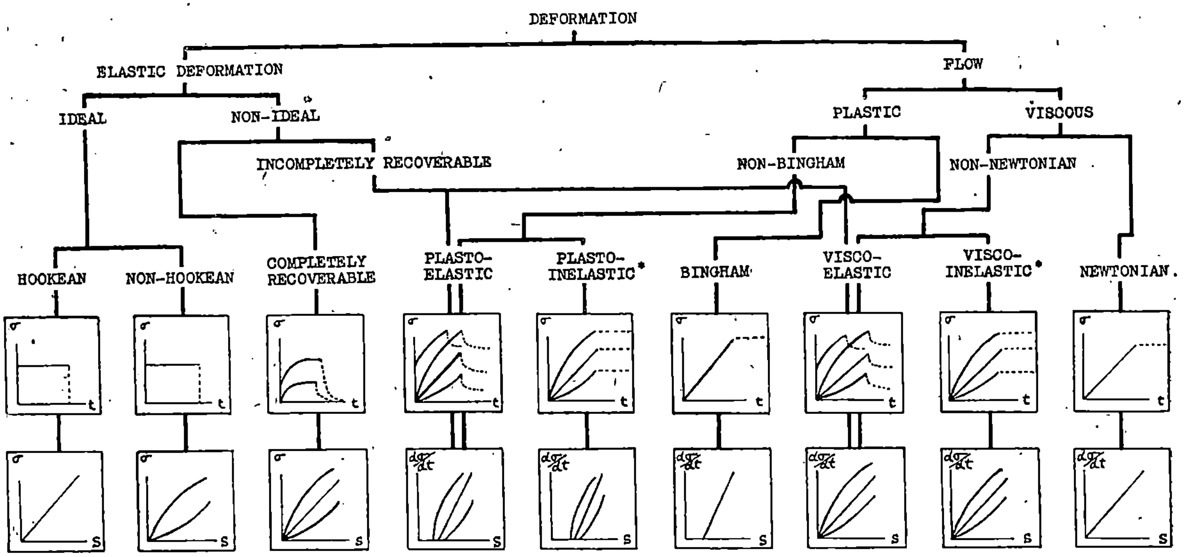
Ionospheric Measurements during Total Solar Eclipse

A. J. HIGGS has published a paper on ionospheric measurements made during the total solar eclipse of October 1, 1940 (*Mon. Not. Roy. Astro. Soc.*, 102, 1) which describes very fully the ionospheric results obtained during the eclipse, with equipment operated at Victoria West, South Africa. The conditions were particularly favourable for settling the question regarding a definite ultra-violet effect and/or corpuscular effect within the F_2 region, because the corpuscular or particle eclipse for particles travelling with the expected velocity of 1,600 km./sec. was due to take place about noon. The F_2 gradient is then generally near its maximum and the diurnal curve flat, so that any corpuscular effect should be more easily detected. In this region it was found that there was no marked corpuscular effect, but that there was an ultra-violet effect. A decrease in maximum ionization density of about 25 per cent was observed, the minimum being reached at approximately 30 minutes after totality, and these results were confirmed by Dr. J. A. Pierce of the Harvard University expedition at Queenstown. The F_1 region was well defined throughout the eclipse, and on the whole it showed the expected results, but the region is more complex than is generally supposed. A subsequent paper will provide detailed examination of the connexion between E region density and size and intensity of bright hydrogen areas. For the present, it can be accepted that the major portion of the ionization responsible for the production of region E was coming, not uniformly from the sun's disk, but from regions near observed clouds of bright hydrogen or calcium. In corroboration of this it may be noticed that observations made by the Carnegie Institution of Washington at the partial eclipse of the sun on April 7, 1940, indicated "that the Sun is not giving out the ultra-violet radiation uniformly from all parts of its surface".

CLASSIFICATION OF RHEOLOGICAL PROPERTIES

AT a meeting of the British Rheologists' Club held at the Imperial College of Science, London, on May 16, the accompanying chart was presented for discussion by the Committee. The discussion was introduced by Dr. V. G. W. Harrison (hon. treasurer).

It is believed that this classification marks a considerable advance on the earlier draft discussed at Birmingham, which was reproduced in NATURE of Feb. 14, p. 197. It incorporates many of the suggestions made by members at that meeting, and also the hatched 'frame' enclosing those categories for which the rate of deformation is liable to increase or decrease with time for constant stress is eliminated. The Committee realized that the use of this frame added considerably to the complexity of the table and that, even with it, the picture was incomplete, since another 'frame' would be required to allow for changes in the strain (σ) — time (*t*) relation with changes in stress (*S*).



(1) σ represents shear strain.
S ,, ,, stress.
t ,, time.

(2) Continuous curves represent deformation under stress.

(3) Dotted curves represent behaviour after removal of stress.

(4) Where two or more curves appear in a diagram, these indicate alternative types of behaviour.

(5) In cases marked * either the σ/*t* curve or the $\frac{d\sigma}{dt}/S$ curve may be a straight line, but not both, since in this case the systems would be Bingham or Newtonian, which are given separate categories.

(6) The upper series of diagrams in which shear strain is plotted against time represents deformations under constant stress. The lower series, in which *d*σ/*dt* is plotted against stress, is for an arbitrary time.

In order to simplify the table, Mr. D. C. Broome had been asked to draw graphs relating σ/*t*, σ/*S* and (*d*σ/*dt*)/*S* for each category showing, where necessary, the possible types of curvature which may occur in each category. These graphs, after slight revision by the Committee, have been included in the revised table. The table has also been re-arranged so that elastic deformations remain on the left-hand side throughout, the viscous and plastic deformations being on the right.

In the discussion which followed, Dr. C. A. Maunder Foster suggested that the Committee might proceed to consider the more detailed drawing of recovery curves and Mr. J. Pryce-Jones proposed that, as soon as possible, examples of materials showing each type of deformation should be quoted. Mr. J. C. Gage doubted whether the insertion of the graphs had adequately replaced the 'frame' of the earlier table.

Dr. J. Needham asked whether the complex rheological properties described by him in a paper read earlier in the day could be fitted into the table, and Mr. L. Bilmes submitted a circular form of the table, which the Committee will consider in the near future.

Replying on behalf of the Committee, Dr. G. W. Scott Blair (hon. secretary) said that he did not think that it would be possible to explain all kinds of complex rheological behaviour in terms of the present table. The Committee has taken as its first task the formulating of a table of types of deformation. It is hoped that with the help of members and of colleagues in the (American) Society of Rheology, the scope of classification of properties may be extended, but for the present the effective range of activity is limited. It is realized that the categories in the table cannot be regarded as hard-and-fast limits of behaviour, but rather as convenient landmarks, analogous in many ways to the psychologist's classifications of character and personality types. It would be rash to regard intermediate systems as, of necessity, mechanical mixtures of the simple types between which they lie. As soon as the categories are found to be acceptable, the Committee will consider the possibility of designating each type by means of a letter or number.

Any one who may wish to make criticisms or suggestions with regard to the above table is invited to communicate with the honorary secretary of the British Rheologists' Club, c/o Institute of Physics, University of Reading.

INSULATING OILS

IN a symposium on insulating oils, five important papers were presented before the Institution of Electrical Engineers in London on May 13 by various authors. In the first one, on "Manufacture and Testing of Oils and Oil-Rosin Saturants for use in Electrical Equipment", A. W. Thompson and J. C. Wood-Mallock described briefly the selection of oil crudes, and the choice of refinery methods best suited for the manufacture of transformer and switch oils, and condenser and cable saturants. Methods of test are discussed and consideration is given to the changes undergone by these liquid dielectrics under high electrical stresses.

Highly paraffinic oils are undesirable in transformers, cables and condensers, and therefore solvent processes are, in general, unsuited to the production of such oils. Rosin is a desirable constituent of cable saturants. It is concluded that in respect of transformer oils, revision of British Standard 148, particularly of the oxidation test, is overdue. Any proposed oxidation test should take account of acidity development as well as sludge, and should be carried out at a lower temperature. Solvent treatments lend themselves to production of transformer oils having the desired characteristics, but the distillate must be chosen for the purpose. For switch oils, further work is required on carbon production during arcing and its relation to refining.

For condenser saturants transformer oil is not ideal. They should be judged on the basis of dielectric loss and stability to ionic bombardment. Sulphuric acid treatment of a naphthenic distillate, which may have a reasonably high viscosity, is the best method of production. In cable saturants for solid-type cables the oil component should be assessed on power loss, particularly at high temperatures, and freedom from gas formation under electrical stress. A suitable oil is prepared from a viscous vacuum distillate from a naphthenic or intermediate crude, by sulphuric acid refining. Solvent processes are unsuitable. Rosin is a desirable constituent because of its effect on gas formation and cable stability, and should be chosen with regard to its effect on dielectric loss.

The second paper, "Insulating Oils for Cables", by S. Beckinsale, indicated the present position in Great Britain of the insulating oils and compounds available for cables, and described their behaviour in impregnating plants. The oils in question are of the paraffinic and naphthenic types, and either class may be used in oil-rosin compounds. Naphthenic oils are the better solvents for rosin and for the oxidized bodies produced from rosins, and their use is increasing rapidly. All the oils and compounds can be prepared with excellent electrical properties, but as some of their constituents are very subject to chemical change in the presence of air, the cable-making plant and processes must be types which reduce this interaction to a minimum. For voltages up to and including 66 kv. the various oil-and-rosin compounds are employed, but for higher voltages either a thin naphthenic oil is used for the oil-filled cables, or a viscous naphthenic oil, sometimes containing a viscous hydrocarbon polymer, is the saturant for the pressure-type cables.

Cable oils should be resistant to gassing, and both British and American oil refiners leave in certain aromatic constituents which absorb any gas that may be generated under electrical stress from the more saturated compounds in the oil. Solvent-refined naphthenic fractions have been found suitable for cables, but the solvent-refined paraffinic fractions have proved unsuitable owing to their failure to absorb gas and to the physical instability of their rosin compounds. The use in Great Britain of oil-rosin compounds for the impregnation of cables for voltages up to 66 kv. is based on their increased viscosity combined with the excellent impregnation and good adhesion between compound and paper fibre. In the early 1920's, papers made from cellulose from the conifers were developed, for it was considered that as resinous substances had been present in the cells in the tree, such cellulose with its characteristic cellular structure would have a greater affinity for rosin than the cellulose produced from such fibres as manila and cotton. The use of this wood pulp has now become almost universal for power cables.

The further improvement of oils and rosins for cables is largely a problem for chemists and physicists, with electrical engineers in the background testing the results obtained from new processes and, where necessary, working out new methods of test as the dielectric losses are reduced.

The third paper of the series, by W. Fordham Cooper, on "Insulating Oil in Relation to Circuit-Breaker Failures", is based upon the author's investigations in the course of the last ten years of a considerable number of accidents and dangerous occurrences due to the explosive failure of oil circuit-breakers and oil-immersed control gear, in the course of which it has become apparent that not all were due to inadequate rupturing capacity or defective insulation. This has been true particularly of a number of failures in recent years of the control gear for arc furnaces. The paper assesses what part deterioration of the switch oil may play, and the importance of the problem may be judged from the fact that oil in such switches is now frequently changed every two or four weeks, and, at some works, once a week.

Many engineers responsible for the maintenance of switchgear have felt that while the tests laid down in British Standard specifications may eliminate many new oils which are definitely unsuitable, they provide no certain guide to the rejection of used oil after a period of service. The author therefore includes a section suggesting the initial tests which might be taken in the search for a more suitable basis. Explosions occur occasionally without previous insulation breakdown or severe arcing, and it is necessary to correlate their occurrences with some definable condition of the oil or the switch.

The study is divided into two parts: (i) surface contamination and the associated presence of suspended matter in the oil; and (ii) general chemical deterioration of the oil. There are then four aspects of each of these, namely, reproduction under controlled conditions of the phenomena observed in the field; laboratory examination of new and used oil, and correlation of the result with experience of breakdown; development of comparatively simple tests for the rejection of seriously defective oil; the determination of whether repeatedly 'cleaning' oil by conventional methods renders it safe for re-use, or whether cumulative effects of chemical change may, after a time, lead to danger. In the initial stages the second and third aspects mentioned above must progress together so that, if possible, a correlation is established between simple tests and those requiring the services of a skilled chemist.

The next contribution is on "Mineral Oil for Transformers and Switchgear", by A. A. Pollitt, in which the author sets out to familiarize the electrical engineer with the nature and characteristics of mineral oils. In spite of the advent of non-inflammable, liquid-chlorinated hydrocarbons, mineral oil still remains the chief dielectric used in liquid-filled transformers and switches. Mineral oil has been chosen because of its high electric strength compared with that of air and because, where necessary, it can function as a cooling medium and so maintain the operating temperature of the equipment at a safe value. The outstanding characteristic of mineral insulating oils is their stability in service. Efficient operation of mineral-oil-filled electrical equipment is dependent, therefore, to a large extent upon the ability of the oil to retain substantially unimpaired, in the presence of deteriorating influences, its initially good electrical properties, its inertness towards the solid insulating materials that are also present in most electrical equipment in which oil is used, and its ability to effect efficient cooling.

The author deals with the constitution of mineral insulating oils, refining, causes of deterioration, oxidation products and their influence, the evaluation of insulating oils, and oils in service.

The last paper, on the "Maintenance of Insulating Oils in the Field", by L. H. Welch, reminds one that insulating oil deteriorates in use and the maintenance engineer must see that the working conditions are such as to minimize this. The oil must be reconditioned when the necessity is revealed by regular observations on its condition. Reference is made to points which should be watched in the design and installation of plant and it is suggested that, of the oils specified in British Standard 148–1933, only grade *B*.30 should be retained. The revised specification should include high-viscosity oils which are frequently used in electrical apparatus. Routine tests for sludge and moisture contamination are universal, but determination of acid value may be important and the flash-point has to be determined occasionally. Suggestions are made as to what values of these should be permitted before purification is considered necessary. The type of contamination likely to be present and the apparatus available for its treatment and various methods of using it are discussed. A table showing suitable maintenance periods is given, and it is pointed out that as it is difficult to handle oil and to work on oil-immersed gear without causing deterioration, these periods depend more on the immersed apparatus requiring attention than on the oil.

Oil maintenance can be kept to a minimum by giving attention to the following points: minimum operating temperature of transformers and kindred apparatus to be ensured by adequate ventilation for indoor equipment and correct adjustments of controls on forced cooling systems; adequacy of breathers, and their maintenance; careful selection of mechanical and electrical design of apparatus, particularly in relation to tap-changing gear; use of grade *B* oils—grade *A* oils have proved liable to develop excessive acidity and sludging in service whereas grade *B* oils have developed less total acidity and less total sludging and should, therefore, be used wherever oil of this viscosity is required; such oils can be expected to prove a reasonable cure for acidity and sludging, which have occurred where grade *A* oils have previously been used; cold purification is much to be preferred and a filter is generally more useful and easier to operate than a centrifuge.

Finally, it is considered that the present British Standard 148 requires revision. It covers six oils of the same viscosity and these could all be replaced by *B*.30 oil. There is need to include other oils, however, particularly a more viscous oil for switchgear.

INSTITUTION OF ELECTRICAL ENGINEERS

THE report of the Council for the year 1941–42 of the Institution of Electrical Engineers discloses that 1,650 new members were elected during the year and that there are now 10,483 corporate members on the register. An Installations Section was inaugurated during the year with an initial membership of 1,127. There are now nine students' sections aggregating a membership of 4,483, which includes 1,944 graduates.

Post-war planning continues to receive attention and a joint committee has been set up consisting of two representatives of each of the three engineering institutions, while contact has also been made by the planning committee with a number of other organizations which are discussing planning problems. Co-operation with the Ministry of Labour and National Service in the working of the Electrical Engineering Section of the Central Register continues and 1,121 members have been placed on work of national importance. Reference is made to the Institution's part in the intensive training courses in engineering, which are designed to carry men from the Ordinary National Certificate to the Higher National Certificate standard in six months. Co-operation with the Institution of Mechanical Engineers has been promoted in this connexion.

More than two thousand members of all classes are on active service with the Forces, and arrangements have been made for ensuring that those liable for military service are posted to appropriate technical branches of the Forces. More than three hundred applicants for technical commissions in the Forces have been dealt with; two hundred cases were presented to the Beveridge Committee with the view of up-grading or transfer to duties in the Services more appropriate to the member's qualifications. More than 4,500 enrolments have been accepted by the War Office from men in the Army and the R.A.F. for tuition in various engineering courses under the scheme set up by the three engineering institutions, the Board of Education and the Service Departments.

Other activities upon which the Institution has been engaged are the preparation of codes of practice, war emergency standards, A.R.P. in the engineering industry, the statistical control of materials and manufactures, and fuel efficiency and economy. On the educational side, in collaboration with the Institutions of Civil and Mechanical Engineers, a joint panel of senior engineers has been formed for the purpose of delivering lectures to university engineering societies, in order to bring students into touch with actual practice. A centre of the Polish Society of Electrical Engineers, with headquarters in London, has been formed and the Institution's premises have been placed at its disposal for meetings, etc.

Associate membership examinations were held for 538 candidates and, in English only, for 193 holders of National Certificates in electrical engineering. Arrangements have been made with the British Red Cross Society for prisoners of war in Germany to sit for the associate membership examination in prison camps. 1,065 national certificates and diplomas in electrical engineering were awarded during the year.

297 books and pamphlets have been added to the Institution's reference library and 58 new volumes to the lending library. Subdivision of the *Journal* came into effect in January 1941, Part 1 being distributed free to members; more than 6,000 members subscribed for Part II and some 4,000 for Part III. *Science Abstracts* continue to be published monthly in two sections, Section 'A', dealing with physics, and Section 'B', with electrical engineering. The universal decimal classification has now been adopted in both sections, as from January 1942. 1,045 copies are issued each month to members and 6,720 copies per month to others.

FOLK-LORE OF VENEREAL DISEASE

IN a recent article (*Brit. J. Ven. Dis.*, 18, 1; 1942) Dr. J. D. Rolleston attributes the scarcity of the folk-lore literature on venereal disease partly to the fact that most medical practitioners know little and care less about folk-lore, and partly to the fact that folk-lorists are rarely medical practitioners and shrink from dealing with what they regard as an unsavoury and repulsive subject. No mention of venereal disease, for example, is to be found in W. G. Black's "Folk-Medicine" (1883) or Sir James Frazer's "Golden Bough" (3rd ed., 1927–36), the two principal works by lay writers, in which much valuable medical folk-lore is to be found, while of the two chief works in Great Britain by medical authors, namely, Pettigrew's "Superstitions Connected with the History and Practice of Medicine and Surgery", published in 1844 or two years before the term 'folk-lore' was invented by William John Thoms, does not mention venereal disease at all, and the comparatively recent work by Dan McKenzie on "The Infancy of Medicine" (1927) has only two brief references to the subject.

The only important treatise on medical folk-lore in which the subject of venereal disease is adequately discussed appears to be that of O. V. Hovorka and A. Kronfeld (1908–9) entitled "Vergleichende Volksmedicin". Owing to the comparatively recent establishment of their autonomy, there does not seem to be any folk-lore connected with chancroid or the fourth, fifth and sixth venereal diseases, so that Dr. Rolleston's paper deals only with syphilis and gonorrhœa.

As regards nomenclature, the term 'syphilis', which was introduced by Fracastoro in 1521, did not at first receive general recognition and during the whole of the seventeenth and eighteenth centuries only about half a dozen writers employed it. Although, however, no scientific term was given to the disease, on its first appearance in Europe a host of new names was introduced by the laity, the commonest being those indicating that the malady had originated in France. Popular theories as to its origin included the views that the disease had a divine source, being a punishment for unchastity, that it was due to intercourse between a man and an animal or that it was caused by intercourse with a woman who was menstruating or had a vaginal discharge of any kind.

Belief in a cure of a disease by transfer of it to another person or animal is a well-recognized tenet of medical folk-lore, but whereas in the case of other complaints such as epilepsy, whooping cough, warts, boils, pulmonary tuberculosis and the acute exanthemata, the transfer is purely imaginary, in venereal disease, especially gonorrhœa, it only too frequently actually takes place without, of course, having any curative effect. The person to whom the disease is transferred is preferably a young virgin of either sex, much less frequently an adult. This superstition, which dates back for several centuries, is world-wide. Other folk-lore methods of treatment for venereal disease include animal and plant remedies and miscellaneous cures which in the case of syphilis include sweating and fumigation, and local application of drugs or other substances. In the case of syphilis but not of gonorrhœa, several patron saints may be invoked, while in gonorrhœa but not in syphilis coprotherapy is sometimes employed.

COLLECTIVE FARMING IN RUSSIA AND THE UKRAINE

SIR JOHN RUSSELL has made a study of Russian agriculture, and, through his visits to that country from time to time, has been able to observe trends in agricultural policy, and the results of the State and of collective farms. He discussed his observations in a lecture recently delivered at the Royal Institution.

It was impossible to arrive at once at the most desirable system of land utilization, this being influenzed by progress in farming methods, particularly as regards mechanization, and the effect of this on the growth of the workers' interest in the State or collective unit, as opposed to his own personal stake in the land. The application of modern machinery to tillage, and of methods of livestock improvement and disease control to herds and flocks are more suited to large than to small units, and it is probable that success in these directions influenced the workers' views as to the extent to which they were prepared to identify their own interests with that of the large unit in which they are employed.

After the Revolution, State farms were developed, but the peasants, who expected nothing less than individual ownership of the land that they tilled, were not then sufficiently mature, either politically or technically, to make a success of this form of organization. Instead of the State farm, the collective farm figured more and more prominently in the development of Soviet land policy. Thus, by 1939, the area occupied by collective farms was more than eleven times that of State farms.

Collectivization is based on the principle that an entire village, with its land, is run by the inhabitants as one farm, boundaries being obliterated, and the whole area divided into a few fields, the number depending on the rotation. All possessions are pooled, and the workers share the produce remaining after paying out the Government share, and meeting other obligations. Collectivization at first met with great opposition, particularly owing to the compulsory pooling of all livestock; peasants who, by years of hard work and economy, had got together a cow and a few pigs, found it difficult to have to restart from the same level as those who had never made any sacrifice to provide their families with livestock necessary to maintain them in milk, butter, and other produce. For this reason, collectivization at first resulted in a heavy decrease in the numbers of livestock. The opposition to collectivization decreased when the benefits of the tractor in large-scale farming were realized, and, later, by the action of the State in securing the land to the collective farm for ever, and in giving to each householder a small plot of land, a cow, one or two pigs and poultry. The peasant of the collective farm is allowed to sell the produce of his plot and of his stock. A worker's time is shared between the collective farm and his own plot, and, in the same way, his income is derived from those two sources.

Sir John gave some data showing the proportion of workers' time spent on the collective farms, the proportion of his total income derived from that source, and the influence of efficiency in the management of the collective on the proportion of his total earnings derived from it. It has become necessary, in some instances, to enforce a minimum of two hundred working days per annum on the collective farm, in order to prevent the peasant from devoting too much of his time to his own plot and stock.

The most important feature of the new system, however, is that production is planned, each farm being told what, and how much, to grow for a period of five years. Requirements are allocated to the different districts, and each farm in the district is allotted its area for the various crops, and told what quantities of animal products are expected of it.

Great efforts are made to utilize science. Thus, extensive soil surveys are carried out, and made use of in developing rotations; one important result of this is a reduction in the area of fallow from 35 per cent under the old three-course system to 20–25 per cent now that rotations are practised. Science also plays a part in the struggle against drought; the importance of this can be understood when it is realized that in large areas in the south the average annual rainfall is not more than 12 inches.

The standard of comfort and of living of the Russian farm workers has not reached that of the British land worker. Houses are smaller, and are not so well furnished. The diet is simple, and would be considered monotonous by many standards. Great strides have been made in education, and by 1939 the ladder was complete, every child having an opportunity of university education.

The author has succeeded in presenting the reader with a brief but clear picture of the lines along which Russian policy is developing. The results of collective farming are discussed, and there is an interesting account of life in a Russian village, or collective farming. E. J. ROBERTS.

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

PATHOLOGIST AND DIRECTOR OF THE CLINICAL RESEARCH LABORATORY—The Secretary and Treasurer, Victoria Infirmary of Glasgow, 40 St. Vincent Place, Glasgow, C.1 (June 27).

MASTER (OR MISTRESS) TO TEACH MATHEMATICS, MECHANICS, SOME SCIENCE, AND ENGLISH at the Junior Technical School of the Wellingborough Technical Institute—The Secretary for Education, County Education Offices, Northampton (June 27).

ASSISTANT SCIENCE MASTER, GRADUATE, TO TEACH PHYSICS PRINCIPALLY, at the Junior Technical School for Boys—The Director of Education, Education Office, Leopold Street, Sheffield 1 (June 27).

TEACHER OF BUILDING CONSTRUCTION, SCIENCE AND MATHEMATICS, at the Oxford Schools of Technology, Art and Commerce, Building Trades and Junior Day Departments—The Chief Education Officer, City Education Offices, 77 George Street, Oxford (June 29).

HONOURS GRADUATE IN ENGINEERING at the Quakers' Yard Technical School—The Director of Education, Education Department, Town Hall, Merthyr Tydfil (June 30).

LECTURER IN CIVIL AND MECHANICAL ENGINEERING—The Secretary, Northampton Polytechnic, St. John Street, London, E.C.1 (June 30).

MISTRESS TO TEACH PHYSICS AND CHEMISTRY at the Wellingborough High School—The Secretary for Education, County Education Offices, Northampton.

ASSISTANT FOR MATHEMATICS, and an ASSISTANT FOR SCIENCE WITH ELECTRICAL ENGINEERING, if possible—The Principal, Technical Institute, Longport Street, Canterbury.

FORTHCOMING EVENTS

Saturday, June 20

INSTITUTE OF PHYSICS (LONDON AND HOME COUNTIES BRANCH) (at the South-West Essex Technical College, Forest Road, Walthamstow, London, E.17), at 2.30 p.m.—Conference on "The Eye in Industry".

Monday, June 22

ROYAL GEOGRAPHICAL SOCIETY (at Kensington Gore, London, S.W.7), at 3 p.m.—Annual General Meeting.

HEALTH SERVICES AND POPULATION PROBLEMS

THERE could be no better illustration of the extent to which the importance of the health of the nation is now generally realized than the general support which the broad policy of the Ministry of Food has received, as indicated in the lecture of Prof. J. C. Drummond on "War-Time Nutrition and its Lessons for the Future" delivered before the Royal Society of Arts on May 6 (*J. Roy. Soc. Arts*, 90, 422, 1942), or than the declaration of some two hundred members of Parliament of all parties in favour of family allowances. Even the General Council of the Trades Union Congress, long the backbone of opposition, is now in favour of a State scheme, and resolutions in favour of a scheme of family allowances, and the right to all forms of medical attention and treatment through a national health service, were passed at the annual conference of the Labour Party in London. The general principle of family allowances in the form of cash payments from national funds was also approved at the Co-operative Congress in Edinburgh on May 25.

The somewhat non-committal memorandum of the Chancellor of the Exchequer (see NATURE, June 13, p. 656) makes its belated appearance when the ground is at any rate cleared for consideration of the application of the general principle to concrete schemes or proposals. This advance in opinion may fairly be attributed to a development in the general outlook on public health corresponding with that which has characterized the medical profession itself in the last two decades, with the change in emphasis from remedial to preventive measures. There is widespread recognition that disease is largely preventible, that malnutrition is a conspicuous factor in many diseases, and that the main causes of malnutrition are ignorance and poverty, with the emphasis on the latter. This undoubtedly has been the chief factor in overcoming opposition to the idea of family allowances. They are welcomed above all as a contribution to the health of the growing generation, and as Prof. Drummond has shown in his lecture, the success of many of the measures adopted to safeguard the nutrition of the nation in war-time is now widely recognized as too valuable to be discarded when victory is won. Prof. Drummond's emphasis on the value of the canteen and of the 'British Restaurant' is supported by a P E P broadsheet on "Health in War-Time" which appeared last year. Like the allotment movement, they can fill as essential a role in peace-time as under war conditions. He sees in these two types of communal restaurant the essence of what might become, with competent handling and appropriate guidance, one of the strongest links in our industrial machine—the health and efficiency of the workers of Great Britain.

It needs but little imagination to realize how powerfully such a development could contribute to that other outstanding matter discussed by Prof. Drummond—education on food and food values.

His lecture gives an inspiring glimpse of the possibilities if such education is not confined to the general population, but is inculcated effectively in the medical and nursing professions. This vision of a campaign to be launched in the United States for promoting good health by ensuring good nutrition holds great implications for Great Britain in agriculture as well as in industry and in health if that example is followed. The consequent expansion of agriculture is exactly of the type which keys in efficiently with town- and country-planning, the reconstruction of the countryside and the most efficient use of our natural resources of land.

Much, it is true, has to be done, as Prof. Drummond himself has shown, before public opinion is ready for such developments. Hospitals and medical men alike in Great Britain are lamentably behind institutions and colleagues in the United States and in Canada in the scientific planning of diet and attention to the prevention of disease by good food. Interest is growing, however, and might be powerfully stimulated by adoption of suggestions such as Prof. Drummond advances in regard to the foundation of chairs in our medical schools for lectures on the prevention of disease in this way as a part of the clinical training of every student, and for the sending out to each of half a dozen countries of small, qualified and equipped teams of young medical men and nutrition experts, trained to correlate on the spot information about diet and the incidence of disease.

Satisfactory evidence of that growing public interest, moreover, is to be found in the debate on hospital administration in the House of Commons on April 21. The question was raised on a motion relating to the regional planning of hospital services by Mr. McNeil, and it was very clear in the debate that the opportunities which the War has given us of establishing out of the Emergency Hospital Service a much more effective hospital service for the whole community are very much in the minds of members of the House of Commons. Mr. McNeil, for example, considers that both in respect of medical and nursing personnel, the War would give us reserves for any expansion on which we might decide; there is in the Services at present a great reservoir of young professional men who will come out with much more administrative experience than their normal professional life would have afforded.

The main emphasis in Mr. McNeil's speech, however, was on the regional aspect of our present hospital system, with reference to the cure and prevention of disease, and the ways in which regionalism can be used to provide the extensions and the elasticity required in our present system. Whatever anxiety may be felt by some local authorities as to the size and pattern of the regional scheme, its administration and finance and its identity with the Civil Defence region, the necessity of regionalism is now generally admitted. Unit borders may require re-definition from time to time in accordance with the re-allocation of industry and the movement of population, and while the existing units of the Emergency Medical Service may well be acceptable for some time to come, in the post-war years the units should at least be open to reconsideration in relation to the planning of physical reconstruction under the Ministry of Works and Planning. Objections to regionalism, as Mr. McNeil suggests, are likely to diminish the more readily with a wise degree of devolution in the administration of the units.

Mr. McNeil stressed the importance of health centres, an efficient educational scheme in health and industrial health officers. Moreover, Mr. Frankel, referring to the announcement that a new site for Charing Cross Hospital has been purchased and that plans are ready, asked for a categorical assurance from the Minister of Health regarding the planning and siting of new hospitals. They must be located in areas where they are most likely to be needed, in accordance with a definite policy intimately related to the building and reconstruction plans being prepared by the Ministry of Works and Planning.

In his reply, the Minister of Health, Mr. Ernest Brown, was scarcely as specific on this point as might be desired, but he reiterated his previous statement as to the Government's intention to continue the partnership between the local authorities and the voluntary hospitals. In affirming his support for a positive and not a negative policy in the field of health, he gave the assurance that the Emergency Hospital Scheme would be fitted into the general scheme. While he declined to commit himself to any definition of the regional unit, it was made clear that the intention is to promote co-operation between a county branch and the teaching or central hospital, and to avoid overlapping and uneconomical expenditure by securing the provision of highly specialized services at teaching hospitals and other centres selected to serve these wider areas, and by arranging for a proper division of functions between the hospitals in those areas. The existing hospital system in the county boroughs, with the exception of a few of the largest towns, cannot provide the enlarged and full facilities in the way of hospital treatment which modern science has put at our disposal, and any attempt to provide them town by town would be grossly uneconomic. In planning our lay-out of hospitals, we must accordingly look to wider areas, said Mr. Brown, and see that all future accommodation provided, whether by municipal or voluntary effort, forms part of a new public health hospital service, set up not haphazard but in accordance with a general design.

The House of Commons debate demonstrated beyond question that the idea of preventive medicine is rapidly gaining ground, and also the general desire to build on existing experience and develop the present system to serve the new needs as they become clearly seen. The same emphasis on the preventive aspects of the health services recurs in a pamphlet on "National Health Services and Preventive Methods for Improving National Health", by Dame Janet Campbell and Dr. H. M. Vernon recently published by the British Association for Labour Legislation. Mr. H. Graham White, in an introduction, directs attention to the implications for a national health policy of the overhaul of our social insurance schemes already in progress—a real extension of national health insurance, reorganization of our hospitals system and a change in the position of the medical profession in the community. Dr. Janet Campbell attempts an analysis of the situation to encourage the ordinary citizen to think out the problem from his own point of view, and to bring an intelligent judgment to bear on whatever schemes may be advanced for reorganized health services to promote better health and higher physical efficiency. From this admirable emphasis on the necessity of educating public opinion, Dr. Campbell's survey of existing services leads her, after an incidental reference to the social factors and services also involved, to discuss the possibilities of a national medical service in which a service of whole-time medical men and women would replace the present panel service by a scheme providing both domiciliary treatment for all who need it and any necessary consultant and hospital services. To secure conditions of work which would be attractive to a first-rate medical man and offer encouragement for reasonable specialization, opportunities for promotion or hospital service, post-graduate study, etc., Dr. Campbell visualizes a unit such as a team of medical men, each specializing in some branch of particular interest to him, and based on a well-equipped clinic or health centre, which would largely replace the out-patient department of the general hospital.

Such a clinic would be supplemented for special purposes by the school clinic, venereal diseases clinic and tuberculosis dispensary, where these are to be found. Dental treatment would be an essential auxiliary service, while physiotherapy, home-surgery and a social service for follow-up work and after-care would be required. Adequate staffing of the clinic would ensure that the medical practitioners had reasonable leisure as well as sufficient time for the needs of each patient and for keeping in touch with the advance of medical science. On the other hand, no patient would fail to obtain prompt medical assistance because of poverty, or be required to pay for special treatment in excess of his capacity.

It would, of course, be necessary to determine how far such a scheme should be available, and also its relations with the public health services. Clearly it cannot be limited to the insured worker. It must be open to all families below a certain income-level, and replace the panel service, the district medical service under public assistance and largely the out-patient work of the general hospital. Moreover, the wider it is open to voluntary contributors able to pay, in part or for the whole of treatment, the stronger would be the financial side of the scheme and the more readily class distinctions would be removed and the disastrous idea of differing standards of treatment for panel and for private patients.

Close and friendly relations with the public health services are essential. Moreover, there are certain duties which might now well be entrusted to general practitioners of the national medical service—Dame Janet Campbell points to school medical work as an example. In regard to administration, while a national medical service would probably be administered by a central Government department and financed from national revenue rather than local rates, she emphasizes the importance of regional and local administration so far as possible, and of the delegation of all purely professional matters to a fully representative medical sub-committee. Her suggestions are reflected in the House of Commons debate, and she reiterates the importance of organizing a national nursing service as part of a national medical service, under which a scheme for the superannuation of nurses who have given recognized services could be established.

There is plenty of evidence that the medical profession itself recognizes the need for reform and reorganization of the medical services. Lord Dawson of Penn's address before the Medical Society of the Military Hospital, Shaftesbury, on "Medicine and the Public Welfare", is only one example of the way in which medical opinion is prepared to consider fundamental changes in the present arrangements and to work out the arrangements which would give us, in a framework planned to secure order but also elasticity, the individuality and freedom which mean life and evolution. Dame Janet scarcely sustains her plea for a Ministry of Medical and Nursing and Social Services, separated from the Ministry of Health, to organize post-war medical reconstruction. With a Minister of Health who is genuinely interested in medical and social questions, and willing and resolute to see the task through, the essential readjustments or transfer of powers between Ministries and Departments could well be better effected by a closer adhesion to the principles of the Machinery of Government Report.

Dr. Vernon's survey in the same pamphlet of preventive methods for improving national health is concerned primarily with industrial health, and he travels over ground which has been covered in several reports from the point of view of production during the last year or so. Social environment, he concludes, is a much more potent factor than occupational environment in controlling the health of the nation, and once again the fundamental importance of social and economic factors in relation to the health of the nation receives emphatic endorsement. It is against such a background that the question of family allowances must now be considered.

The Chancellor of the Exchequer's White Paper of May 7 endeavours to show the fiscal cost of a five-shilling-a-week allowance, now that for important sections of otherwise widely divided opinion the question of relating income to the extent of family responsibilities by means of family allowances has become, not whether there should be a scheme, but how best it can be applied. On such points as the cost of a scheme, its financial resources, its administration, its relation to existing partial schemes and how it could be supplemented by voluntary schemes, the White Paper supplies facts and figures. It is clear that the difference between the cost of allowances with a means test and allowances to all children is slight, compared with the total cost. This should be decisive in view of the objection of the Trades Union General Council to any scheme involving a means test, against which there is much to be said on the ground both of equality and simplicity, particularly when the expenditure should be socially productive.

Much the same objections would apply to any contributory scheme, and if a reduction in cost is considered imperative, the most effective and practicable method would probably be to withhold the benefit from small families. There are precedents in the schemes of other countries for excluding the first child, but the social surveys in recent years which have brought out the relation between size of family and the poverty line have put the case for family allowances as a remedy for poverty on such a new footing that a generous scheme may well be the soundest policy. Moreover, the population situation provides a powerful argument for a generous scheme. Before reaching a decision at the present it would clearly be desirable, as the Chancellor points out, to explore the alternatives to a system of cash allowances, when the problem may be less one of cash than of supplies—alternatives which the White Paper unfortunately does not proceed to examine. Nevertheless, the Government could scarcely take any single step open to immediate adoption that would go so far as a system of family allowances both to mitigate poverty in its most distressing form, and to convince public opinion that it is taking serious thought for the future generation and is prepared to undertake far-reaching reorganization and development of the health and related social services.

ALFRED NORTH WHITEHEAD

The Philosophy of Alfred North Whitehead

Edited by Paul Arthur Schilpp. (The Library of Living Philosophers, Vol. 3.) Pp. xix+745. (Evanston and Chicago: Northwestern University, 1941.) 4 dollars.

THIS volume provides a guide to Whitehead's published writings, an explanatory commentary upon them, and criticisms of the objections to which they may be considered to lie open. It had been hoped that Whitehead would reply to the criticisms. Unfortunately a serious illness has prevented him from doing so. Instead he has contributed some delightfully characteristic "Autobiographical Notes", and a letter (reproduced in facsimile) in which he has suggested that the outcome of this volume, had health and age allowed, would have consisted in his "devoting many years to rewriting [his] previous works". Two of his philosophical papers, not previously published, are also given, on "Mathematics and the Good", and on "Immortality".

The twelve autobiographical pages are a treasure in themselves; and happily the setting is worthy of them. The expository and critical articles, making up the body of the volume, are eighteen in number. Partly by pupils and disciples, but mainly by scientific and philosophical colleagues in the United States and Great Britain, they one and all aim at a *critical* account of Whitehead's teaching. Much the longest (pp. 15–125), and also quite the most important, of all the contributions is that of Victor Lowe on the "Development of Whitehead's Philosophy". It is an interpretation and critical discussion of the successive phases of Whitehead's teaching as recorded in his published writings alike in the pre-philosophical period that opened with his "Treatise on Universal Algebra" (1898) and in the series of philosophical works that opened with his "Enquiry Concerning the Principles of Natural Knowledge" (1919). Dr. Lowe answers many questions which must have been in the minds of Whitehead's readers; and on those other questions in regard to which he can at best express only doubts and difficulties, he has been able to define the issues with a definiteness and clarity that is most helpful. He has also been able, as have several of the other contributors, to make very enlightening use of supplementary comments received directly from Whitehead in the course of his teaching or in private discussions. To Lowe, in collaboration with R. C. Baldwin, is also due a remarkably complete Whitehead bibliography (inclusive of "selected reviews"), compiled despite the many difficulties occasioned by the War.

Whitehead, in the "Autobiographical Notes", after an account of his schooling in "classics, interspersed with mathematics" at Sherborne—the classics, he remarks, were well taught—tells of his life in Cambridge. "During my whole undergraduate period at Trinity, all my lectures were on mathematics, pure and applied. I never went inside another lecture room". But the lectures, he adds, were only one side of his education. "The missing portions were supplied by incessant conversation, with our friends, undergraduates, or members of staff. . . . We discussed everything—politics, religion, philosophy, literature—with a bias towards literature. This experience led to a large amount of miscellaneous reading. For example, by the time that I gained my fellowship in 1885 I nearly knew by heart parts of Kant's *Critique of Pure Reason*. Now I have forgotten it, because I was early disenchanted. I have never been able to read Hegel: I initiated my attempt by studying some remarks of his on mathematics which struck me as complete nonsense. It was foolish of me, but I am not writing to explain my good sense".

These sidelights on his early studies go far in explaining what would otherwise be so difficult to understand: the seeming abruptness of Whitehead's transition from a philosophy of science to metaphysics "Whitehead is very English. He is also very Whiteheadean: he could not have done otherwise. What might, by critics at least, be called the contribution to his philosophy that comes from his *amateur* side, has been a subject of meditation for decades; this appears plainly in every account of his life's activities". This is the central theme of Lowe's historical and critical account of Whitehead's development. He distinguishes in it three main periods: a first devoted to mathematical and logical investigations (up to 1914), a second to the philosophy of natural science (1914–24), and a third to metaphysics and the historical role of metaphysical ideas in civilization (1925 onwards). In the second period Whitehead has been chiefly concerned to achieve the integral inclusion of geometry in the world of change, and to do so without yielding to the anti-space bias betrayed by Bergson. As Lowe recognizes, what especially calls for explanatory comment, in regard to these second and third periods, is: (1) Whitehead's gradual divergence from the 'class-theory' of perceptual objects (as held by him in common with Russell) and adoption in its place of a 'control-theory' of physical objects; and (2) Whitehead's ever-increasing preoccupation with metaphysical issues, and the tendencies seemingly (but not in actual fact) anti-intellectualist, which accompany and condition it.

Already in the papers published between 1915 and 1917, as Lowe points out (p. 61) "un-Russellian, un-Humean, un-positivistic traits" are discernible. But these traits, and the direction in which they were leading Whitehead, though partially disclosed in the "Principles of Natural Knowledge" (notably in its superb opening chapter) and in the "Concept of Nature", first became clear only on the publication of "Science and the Modern World" (1925)—a work the teaching of which alienated so many of his older associates, while attracting the attention of a new and wider audience. Even so, the clearness is indeed relative; the middle, metaphysical, chapters were found barely understandable even by some of the best instructed of his readers, and had to await, for their decipherment, the more detailed and in certain important respects modified, formulation of them in his subsequent writings. The continuing ferment in his ideas, as Lowe recognizes, has "interfered with their bottling", and as Lowe justly adds, "this remark applies in some degree to every part of Whitehead's works". Fundamental in Whitehead's defence of metaphysics, in what he considers to be its proper role, namely, as a constant critic of partial formulations, is his attitude of opposition to "the false neatness of *abstract* intellectualism", that is, to the assumption that there is an already existing stock of concepts, at once general and precise, on hand for use by scientists and philosophers. He is not intending to deny the necessity of abstraction for the purposes of science, but he is anxious to insist that just for this reason metaphysics cannot be dispensed with if "a right adjustment of abstractions" is to be made. "This is missed by the critics who think that Whitehead denies the principles of scientific method when he turns philosopher. Far from making general war on acts of abstraction, he insists that such acts are indispensable to the advance of thought. What he objects to is a bigoted insistence that only fools investigate the totality from which the abstraction has been made. If philosophers keep to the same abstractions that sciences make, they are scientists in disguise, or possibly pseudo-scientists who happen to earn their living by teaching philosophy. If a man of Whitehead's ability delves behind the abstractions made by particular sciences, it becomes possible for philosophy to 'point out fields for research'. Whitehead thinks that the *development* of those fields must be assigned to specialists".

The other seventeen papers cover all the main aspects of Whitehead's teaching. Joseph Needham treats of "A Biologist's View of Whitehead's Philosophy", and A. D. Ritchie of "Whitehead's Defence of Speculative Reason". The other essays are all by American contributors, including the veteran John Dewey. The average maintained is extraordinarily high, but I may specially mention the paper on "Whitehead and the Method of Speculative Philosophy" by A. E. Murphy and the paper treating of "Whitehead on Mind and Nature" by W. E. Hocking, because of their consistently critical character and of their dealing with really decisive issues. Hocking's attitude is summed up in the very apt comment—"Whitehead's construction springs from a striking freshness of impression achieved against the pressure of a 'learned tradition' which it is one of his pleasantries to put in its place . . . giving rather like an era than a single individual a flood of impulse and a gallery of inchoate conceptual forms. It is a human gift to be able to acquire naïveté; it is what Lao Tze called 'returning to the root': to do so to this extent is, in my judgment, as important a deed as to set up an impeccable list of primitive notions".

N. Kemp Smith.

SOCIAL REPORTING

An Inquiry into British War Production

Part 1: People in Production. An Advertising Service Guild Report prepared by Mass-Observation. (*Bulletin of the Advertising Service Guild*, Change No. 3.) Pp. 410. (London: John Murray, 1942.) 10*s*. net.

THIS report shows clearly that Mass-Observation should be considered as a challenge to journalism rather than to the social sciences. What it offers is a comprehensive description of present-day industrial life in much of its concrete detail. Considered as a scientific study, its superficiality and subjectivity could not be excused on the ground of its extensive range. As a kind of expanded reporting, on the other hand, it develops one of the suggested functions of journalism much beyond what the Press has so far achieved.

The chief method employed was that of interviewing people in all grades of war industry, including the management, the foremen, skilled and unskilled workers, trade unionists, and Civil servants in the Supply Ministries. News items from the Press, anecdotes, and reports from diarists working for Mass-Observation supplement these interviews; now and again the numerical results of a canvass of opinion are included, though no claim is made to the validity of bigger surveys such as the Gallup polls. The topics studied include most of those which crop up in everyday discussions on the use of man-power: hours of work, wages, absenteeism, shopping, billeting of imported workers, sickness, discipline and the Essential Work Order, suspicion as to the profit motive of employers, the outlook and prospects of women workers, the worker's difficulty in realizing the value of his particular job in the war effort, and so forth. Emerging from the survey of most of these problems is the evident need for everybody to understand more fully what other people are doing and the conditions of their work. The Fighting Services, the Supply Ministries, management, foremen and workers all need to know more about each other. Extensive reporting of the kind offered here is one means of fulfilling the need.

Minor defects, such as an occasionally patronizing manner and a seemingly compulsive need to aim pinpricks at those in authority (especially academic authority), are of small account compared with the possibilities of this developing technique. An unsolved problem in this type of reporting is the form in which it should be published. The present report is inordinately discursive and tedious to read. Crisper writing and much briefer comment and interpretation would help. But some form of serializing would be a still greater advantage; a cumulative picture of present-day conditions, built up week by week and continuously modified, would be assimilated more effectively than an occasional report of 200,000 words.

Though not in itself a scientific study, the report shows, as good journalism should, the relevance of current scientific ideas to its observations. The findings of industrial psychologists since the War of 1914–18 are the active ingredients, the leaven in the mass. It is a tribute to the Industrial Health Research Board, the National Institute of Industrial Psychology, and Elton Mayo and his American co-workers, that practically every interpretation and suggestion in this report is derived from the work they have already done. Not all the relevant contributions of industrial psychology are used, however. In particular, our knowledge of the psycho-neuroses in industry, which would have illuminated some of the material presented here, is not drawn upon.

The practical implication of the report is, not unexpectedly, that the human factor in the war industries presents sharp challenges at many points, and that the available resources of the social sciences have not been mobilized to meet them. The author is perhaps too prone to believe that, in his own words, "*Something* is seriously wrong somewhere." What the report shows is quite different; namely, that countless relatively small mistakes are being made everywhere, an ordinary state of human affairs. The difference is important, since the first point of view invites the facile deduction that *something* (usually something political) would put everything right, a conclusion which experience in the applied social sciences does not encourage.

CONFESSIONS OF A CHEMIST

Souvenirs et travaux d'un chimiste

Par Amé Pictet. Pp. 228. (Neuchâtel : Les Editions de la Baconnière, 1941.) 9 francs.

THE posthumous appearance of this autobiography of Amé Pictet, written without any directions as to its publication and, to judge from its outspoken nature, clearly intended for an intimate family circle and friends, is a noteworthy event and a fitting complement to the many appreciative notices of the man which have appeared since his death. Of the appropriateness of the decision of those who facilitated the appearance in print of what, in the minds of many, will be regarded as an interesting historical gem, there can be little question. All chemists, old and young, will profit by a perusal of these frank pages.

Pictet was a great organic chemist who belonged to the nineteenth and twentieth centuries and to the borderland of France and Germany. As a Swiss he received his early education in his own country, but his mature chemical education was completed by three years sojourn in Germany, at Dresden under Schmitt, where he was contemporary with Hantzsch, Curtius and Berlinerblau, and at Bonn under Kekulé and Anschütz. He also spent a short time in Wurtz's laboratory in Paris, where he made the acquaintance of Friedel, Grimaux and Lecoq de Boisbaudran.

Pictet's habit of keeping a diary which he began as a youth, and his craze for documentation, both of which he kept up until his death, have left us a priceless record of the impressions which the events of his life made upon him at the time of their occurrence. It is this candid intimate touch which is such a valuable feature of the work before us. Naturally Swiss chemistry, the Ecole de Chimie and the University of Geneva loom large in its pages, but not obtrusively so. Of his childhood and boyhood days with his parents, aunts and uncles, we are told just what one might have expected to find in an educated late-Victorian English family; the excursions of the female members of the family into phrenology and other pseudo-sciences added to his education but not to his beliefs. Throughout his career, his hopes and fears, his successes and failures, the effect of his discourses on his audiences and on himself are all faithfully and refreshingly recorded. One might have thought that his German training would have given Pictet a bias towards German science, but in these pages an undercurrent frequently comes to the surface, making it clear that he was sensitive to the existence of the unhealthy atmosphere in Franco-German relationship extending even to things scientific, and he states clearly that his leanings are towards the French outlook on science. In his diary Pictet records, during his studies at Dresden, his surprise that the Germans should ignore the discoveries made in France, but is happy to see that the same does not apply to Swiss discoveries, and he naïvely adds: "ce n'est que l'attention des Allemands qu'il importe de s'attirer dans le domaine scientifique."

Of his predecessor in the chair of chemistry at Geneva, Graebe, and of Kekulé, several characteristic anecdotes are recorded. Kekulé, interviewing a young French student in his study, asked him if he knew German, and on receiving a negative reply, impressed on the Frenchman that to practise chemistry it is absolutely essential that one should know German. Graebe, on his retirement, went to live at Frankfort, where Pictet called upon him in his old age. After failing at first to recognize his former colleague, Graebe gradually recovered himself and asked: "What are you still doing in organic chemistry? It's a science which is exhausted."

One of the attractive features of this little volume is Pictet's review of his own researches. The methods he employed were all simple; pyrogenic distillations figure largely, and all his researches have a thread of continuity running through them. His introduction to heterocyclic chemistry and alkaloidal chemistry was more or less accidental. One day at Bonn he was passing a bookshop when he saw a brochure of Königs' open at an article on pyridine, with its proposed formula portrayed. The analogy with benzene so struck Pictet that he resolved to devote his career to this new class of aromatic heterocyclic compounds. This led him into alkaloidal chemistry, and he seems to have been the first to write a book on alkaloids. Its success led to a demand for its translation into English and German—the fate of subsequent German editions must be left to the reader to discover for himself. On the synthesis of nicotine Pictet spent eight years, and he recalls that his views on the genesis of the alkaloids in plants, from protein breakdown products, came to him in a flash when chatting with his assistant Rotschy so early as 1904. His subsequent experiment on the distillation of coal in a vacuum was prompted by a desire to find 'fossilized alkaloids', and it was but a step to subject vegetable substances, which might have given rise to coal, to pyrogenic distillation under reduced pressure. The distillation of cellulose gave him lævoglucosan, and this was naturally followed by the distillation of the sugars.

Organic chemists who are familiar with the history of organic syntheses in the past twenty years will naturally turn to Pictet's own account of the synthesis of berberine, which he published with Gams, and of sucrose, published with Vogel. Both these are discussed and the failures of others to confirm them are fully recognized. He seems to have become reconciled to the incorrectness of the berberine synthesis, but the failure of numerous workers to confirm the synthesis of sucrose was a bitter blow, which threatened to undermine his health. Even to the last he never gave up hope that some one, some day, would rediscover the conditions which lead to a successful synthesis, a hope which he did not live to see fulfilled.

HAROLD KING.

CAN WE ANALYSE OURSELVES?

A Practical Method of Self-Analysis

Enabling Anyone to become Deeply Psycho-Analyzed without a Personal Analyst. By Dr. E. Pickworth Farrow. Pp. xv+154. (London: George Allen and Unwin, Ltd., 1942.) 6*s*. net.

THE author of this book, a doctor of science, sought analysis both as a means of cure for his emotional difficulties and as a scientific experiment. After two hundred hours of work under two analysts, with whom he got at cross purposes, he came upon a method of self-analysis, a writing down of his own free associations, which enabled him to recover early memories—potent in causing his difficulties—the recovery of which brought decidedly beneficial results. This experience he now offers as an encouragement to others to do likewise.

He anticipates and answers some possible objections, but the success of the would-be self-analyser may not be so certain as the author hopes, even with full devotion of time and patience to the effort. Individuals vary greatly in their ability to produce free associations and to recognize the meanings of their own symbolisms. The reviewer knows of two cases in which, after a short experience with an analyst, the analysand was able to carry on in the way here described and bring to light important episodes with an appreciation of their emotional value; both subjects were trained in scientific method and one of them started analysis full of scepticism. But there are many people who lack this ability, even in the presence of an urgent need for the relief of symptoms, and are likely to fail at self-analysis. The author seems to credit mankind in general with his own capabilities, as if someone with a natural bent for mathematics should assume that we all have powers in that direction equal to his own. This tendency to picture others as like himself runs through the book. His own crucial memories are concerned with slaps and blows in infancy and with a severe castration threat which, when revived, produced in his adult mind a state of worry and fright "worse than in the worst nightmare", followed, however, by a great improvement in health and a different view of life. These two complexes are the chief, almost the only, findings of his analysis.

A failure to revive elements apart from these physical hurts or threats is perhaps responsible for a passage that calls for comment. His admonitions as to the ill-effects of slaps and blows and castration threats are useful and necessary, but those in charge of small boys guilty of exhibitionism are to be instructed that the child is to be repeatedly told that *this is very naughty* and that he must not do it, and if this fails the fact is to be reported to the parents. It would be less dangerous and more in accord with truth to say that people *think* it is very naughty, for the full weight of our irrational sex taboo, with the terrible dread of an unknown penalty wrapped in it, is thrust upon the child in that italicized sentence. The taboo exists and we all, young and old, must adapt to it; but those able to explain it to a child find it can be accepted and understood for what it is. In its primitive and unquestioned form it strengthens the unconscious guilt that underlies so much neurotic trouble and it sends many an adult to the consulting-room of the psychotherapist.

The author goes on to indicate his orthodox adult attitude towards infantile sexuality when, instead of the castration threat, he advocates moderate slapping on the buttocks as conducing to the subsequent mental health and stability of the young exhibitionist! Another gap in his analysis concerns the transference—the emotional attitude, positive or negative, towards the analyst—that enables the subject to recapture and work out his infantile emotions. The author frankly admits his non-recognition of this situation; perhaps, if he had accepted the invitation of his second analyst to curse him freely instead of breaking off the analysis, he might have recognized the importance of the transference and its usefulness as an emotional solvent.

In spite of these defects this account of the results of analysis from the point of view of the analysed is most useful. Analysts generally prefer that their subjects should not read the literature; the author's avoidance of anything but passing reference to matters of theory outside his own experience lessens any such objection in this case; his descriptions are straightforward and he uses few technical terms; and even if his avowed aim may rarely succeed, he has produced a book that could very well be read by anyone who contemplates analysis but is still frightened by the bogies of past controversy.

MILLAIS CULPIN.

SCIENTIFIC AIDS FOR THE LAYMAN

Dictionary of Scientific Terms as used in the Various Sciences

By Surgeon Rear-Admiral C. M. Beadnell. (The Thinker's Library, No. 65.) Second edition revised and with Supplement. Pp. x+232+14. (London: Watts and Co., Ltd., 1942.) 2*s*. net.

The Origin of the Kiss: and other Scientific Diversions

By Surgeon Rear-Admiral C. M. Beadnell. (The Thinker's Library, No. 89.) Pp. x+117. (London: Watts and Co., Ltd., 1942.) 2*s*. net.

ADMIRAL BEADNELL'S "Dictionary of Scientific Terms" was first published four years ago, and was warmly welcomed by high authorities for its comprehensiveness, its accuracy and its utility. A new edition having been called for, the book now appears in a revised and extended form. Its chief appeal is to the layman, whom the author has mainly in view. But the vast domain of science necessitates an increasing degree of specialism, and we have it on the authority of distinguished specialists that this concise dictionary is useful to others besides the layman. The latter, however, in the course of his general reading, wants something more than the ordinary dictionary tells him about hormones and vitamins, about wave-lengths, and about the size and weight not only of protons, electrons and atoms, but also of the earth, the solar system and the Milky

Way. Or he may want facts concerning cosmic rays, dwarf stars, the density of space, the mysteries of life and sex, the fertilization of flowers by snails, bats and birds, and a hundred other topics that come to the eye as one turns the pages of this little book. It is a marvellous florin's worth, and well deserves continued success.

The same author's new book, "The Origin of the Kiss: and other Scientific Diversions", is a still more determined effort to help the layman, but with direct reference to the harassing times in which we live. Mental as well as physical relaxation was never more needed than now. People, says the author in effect, want, and rightly want, to be "taken out of themselves", to find means of "escape". Tales of adventure, detective stories and thrillers all serve this beneficent purpose, but for many people they begin to pall, and a craving is felt for something more sustaining. Here Admiral Beadnell comes to the rescue. He seeks to "arouse interest in the 'brass tacks' of the universe, in the way in which so many of man's inventions, not excluding guns and projectiles, camouflage and smoke-clouds, have been forestalled by lower animals, and in the deep significance underlying such apparently trivial matters as kissing, dancing, laughing and flying into a temper". In his twenty chapters the author gives the reader twenty exhilarating excursions into the realms of biology and anthropology, and will probably leave him asking for more.

T. RAYMONT.

CHEMISTRY AND LIGHT

The Chemical Aspects of Light

By E. J. Bowen. Pp. vii+192. (Oxford: Clarendon Press; London: Oxford University Press, 1942.) 12*s.* 6*d.* net.

ALTHOUGH a number of treatises suitable for specialists have recently appeared, there has hitherto been no English text-book on photochemistry and allied subjects which meets the needs of first- and second-year students. Lecturers and students will be grateful to Mr. Bowen for writing a book of which the need has been apparent for so long. In presenting a complete outline of the present state of our knowledge of the interaction of light and matter, the book will also be valuable to the non-specialist and the advanced student, whose sense of perspective is liable to be obscured by detailed study of parts of the subject.

The book opens with an account of the general properties of wave motion and the interaction of electromagnetic waves and matter in classical terms. Chapter 2 deals mainly with practical matters—light sources, units of intensity, etc., and photometry, but includes a short account of black body radiation, with the Stefan and Planck laws, although these are not mentioned by name. This is followed by a comprehensive chapter on the absorption and emission of light. In the main this is a summary of the conclusions of wave mechanics about atomic and molecular energy-levels, transition probabilities and molecular structure. Features of this chapter are the admirable description of the photochemistry of hydrogen, oxygen, chlorine and hydrogen iodide in terms of the familiar potential energy diagrams, and the sections on light absorption by polyatomic molecules, and condensed states. Chapter 4 discusses the important question as to what is the fate of light energy absorbed by a molecule. External and internal deactivation are elegantly explained, and there are discussions of the nature of collisional processes, fluorescence and resonance radiation, and the Raman effect.

In my opinion the arrangement of the book would have been improved if this had been followed at once with Chapters 6 (photochemical reactions) and 11 (chemiluminescence), instead of the chapter on luminescence of solids. The section on photochemical reactions includes practical details, and an account of the collision and transition state theories of reaction, relevant to the discussion of secondary reactions. It is rather surprising that no reference is made, either in this or earlier chapters, to Einstein's law of photochemical equivalence, which was of fundamental importance in the understanding of the process of light absorption. The author points out the uncertainties of bond energies in polyatomic molecules; it might have been mentioned that the carbon arc method is not the only one available for determining the heat of sublimation of carbon. Examples of photoreactions given include the H_2—Br_2, H_2—O_2 reactions, and the photodissociation of NH_3 and the carbonyl compounds.

The remaining chapters of the book give interesting accounts of subjects which do not appear to have been collected together before: photosynthesis in plants, the photographic process, the reactions of the eye to light, and photo cells. In addition, there are appendixes on the preparation of light filters for isolation of lines of discharge lamps, the practical determination of quantum efficiency and the preparation of phosphors. The collected data on light filters should prove extremely useful to the practical photochemist. References to summaries of earlier work are also given.

It will be seen that Mr. Bowen has compressed an enormous amount of material into 186 pages. Throughout the treatment is descriptive and non-mathematical, and maintains a nice balance between theory and practice.

C. H. BAMFORD.

A BOOK OF VISIONS

Primitive Scenes and Festivals

By Sacheverell Sitwell. Pp. xii+283+16 plates. (London: Faber and Faber, Ltd., 1942.) 21*s.* net.

IF any reader should take this for a book of anthropology or archæology, aiming at completeness of treatment and full references to authorities, and feel himself rather upset by the general discursiveness of the whole, the author is not to blame. He tells us very plainly that he writes of what he has studied "with the eyes of the poet or the artist;" the matter of the book is "a subject for a composition, to be judged by intrinsic, not by literal truth". We have in fact a book in which a poet has set down the reactions he has had from his reading and one suspects from his travels, and the reader has only to ask himself if this aim of beauty has been achieved. The appeal is personal: to me it seems that Mr. Sitwell has here scored a fresh success in this very individual kind of writing which he had tried in several other of his books: the series, I think, began with "The Gothick North" in 1929. These "Primitive Scenes and Festivals" are culled over the widest range possible: in time from the days of Stonehenge to the present; in space we are led by our guide from our own islands to Greece and North

America, from the Pacific to many parts of Europe, and all this in less than three hundred pages. The result is a series of highly coloured descriptive reveries, only to be judged by the pleasure felt by the reader in the author's artistic integrity, for his own expression "intrinsic truth" seems to mean nothing very different from this. So Pater summed up his chapter on Lacedæmon: 'Another day-dream,' you may say, about those obscure ancient people, though he claimed, as I think Mr. Sitwell might well do, that his dream followed naturally on the facts as we are able to know them.

I have found the book stirring and delightful: even over pages where the reader is likely to feel a little bewildered, he is carried forward by the poetical intensity of the author's style. Here I am thinking mostly of Book I: "Landscape of the Megaliths"; to get the best of these out-of-door scenes one should read the chapter right through, and then turn to Blake's illustrations to the "Pastorals of Virgil". If this style of writing, which Mr. Sitwell has made so much his own, does sometimes seem strained—and almost to breaking point—it is only when he chooses a subject which fails to inspire, if not the writer, yet the reader. It is difficult to follow the melody, in fact not to skip, when one is confronted by pages and pages on the markings of fancy pigeons. Yet a very similar piece in "The Dance of the Quick and the Dead", devoted to the varieties of Auricula and Polyanthus cultivated by miners and weavers in Lancashire, has a most touching charm: the flight is shorter, and the human interest is much greater; and after all, these fancy pigeons are such monstrous objects.

To dwell a little on what one thinks the best chapters is a pleasure which could be prolonged at will. I was most struck by the account of the Oracle of Dodona, even though it is the doves which are made the occasion of the dissertation on fancy pigeons. No page in the book is more exciting than the description of the beating of the cauldrons to make them ring, as they hang from the trees of the wood. Mr. Sitwell artfully conceals his learning, and how far he has studied the works of Sir James Frazer and Dr. A. B. Cook I do not know, but I find one curious point in which the poet and the scholar have come very close to one another: it is on the word "Dodona". Mr. Sitwell speaks of "the dark feminity" of the name; Dr. Cook has a surmise that it is in some way a reduplicated form connected with "Demeter". The whole description of the place is as evocative of something very distant as the Homeric line: "O King Zeus, of the Pelasgians, at Dodona, dwelling afar." So remote is the oracular valley that it must always be a long ride to Dodona.

There is a terrifying account of the human sacrifices on the stepped pyramid, the Great Teocalli, in Mexico: Mr. Sitwell has a taste for the grim. He shows us the executioner priests living on the top of their pyramid; never coming down except to snatch their victims as they ascend the winding way; exposed to all weathers in a kind of vultures' eyrie of blood and filth. Though nothing is spared, the passage is justified by its wider outlook, but it does remind us of the account of the prison system in "The Dance of the Quick and the Dead", which for sheer dreadfulness can scarcely be read without the pains of a claustrophobic nightmare. In a happier vein is the chapter on the Areöis, the Sea Gypsies, who, like 'playboys' of the Pacific, used to go in their canoes from island to island, entertaining the people with their songs and dances. They were a part of that old, childishly beautiful, if sometimes cruel, world of the islands before the traders and missionaries came to make us ashamed of what we have done to these unhappy children. By our acts, through the greed of the whites, they have, as Mr. Sitwell puts it, "fallen out of an earthly paradise into a Sunday slum, the conch shell made silent by the harmonium". "We could have wished it was but an interlude, a day and a night in prison; but what it touched has been destroyed for ever. It has been the hand of death: and, in life, it is better not to think of that." The poet can only turn his back; sadly.

Book VII is called "The Festival at Nola." It is a description of the feast of St. Paulinus, when *guglie*, "lilies", tall baroque obelisks decorated in all sorts of ways, are carried through the streets. Mr. Sitwell introduces speculations that this festival originated in the rites of Adonis, and certainly the dancer who faints and pretends to die and is then suddenly revived is very remarkable. But here, and perhaps here alone in the book, we ought to have been told a good deal more if such speculations are to be fruitful. We must take into consideration the fact that these processional towers or obelisks are not peculiar to Nola: they are to be found at Gubbio, at Viterbo, and at several other places in Italy. Any quantity of learning about them is to be found in Dr. Thomas Ashby's book, "Some Italian Scenes and Festivals". It may be admitted, however, that these ideas about Adonis are just as good as the old suggestion that the towers at Gubbio are a survival of the ritual described on the Iguvine tablets. To me the *guglie* seem to be simply triumphal cars of the same family as the *carroccio* at Florence, only enormously developed in the vertical direction to suit the narrow winding streets of old Italian towns.

We are given sixteen good and well-chosen illustrations; the only one in the faintest degree hackneyed is the picture of the Lion Gate at Mycenæ, and perhaps this is not so familiar to everyone as it is to travellers in Greece. What could be more delightful than the drawings from Catlin? The Crow Indians on horseback, and the delicate picture of the Indian chief, Mahtotohpa, of whose death we are given so tragic an account: all his tribe were dead of smallpox; he alone had been strong enough to recover; then, left all alone, he starved himself to death. But is there not in fact a certain incongruity in illustrating a book like this at all? When we are so much in the hands of the writer, we do not greatly care to see what lies behind and below; when we are, so to say, in the palace of art, we may well be content to let the foundations be hidden. To ask for illustrations is rather too much like demanding references to authorities. Perhaps the true illustrator would be a double of Mr. Sitwell himself, but armed with a brush instead of a pen.

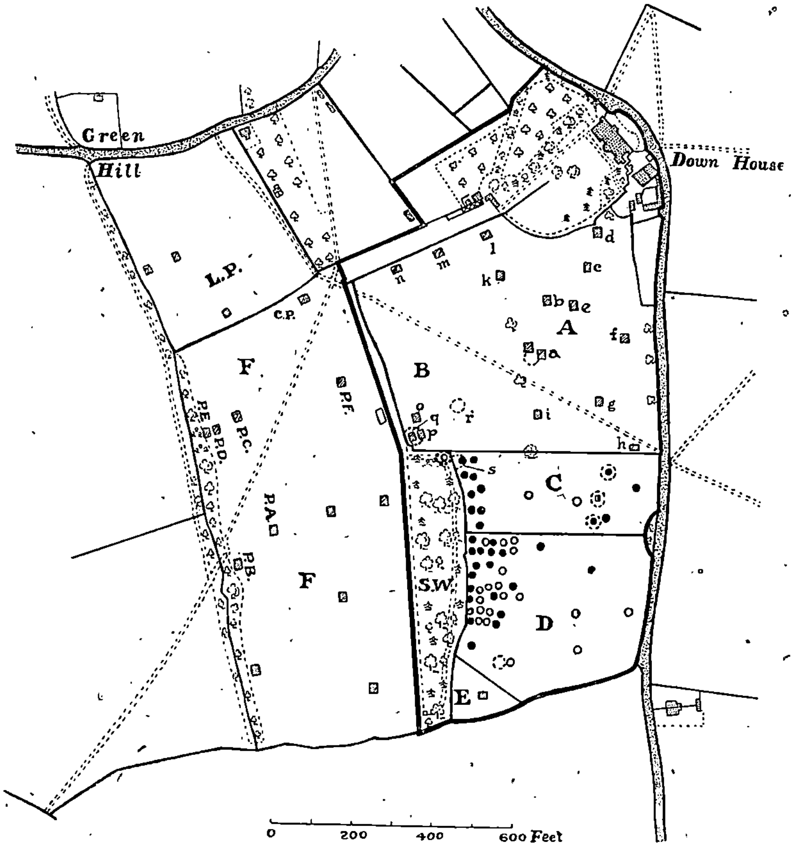
In this review I have tried to give some idea of the scope and intention, as I see them, of this book, and I am very far from having exhausted the subject: other readers would quite likely make quite other choices, after their walk, if one may use the metaphor, through the gallery which Mr. Sitwell, an artist of the greatest virtuosity, has hung with his latest pictures, with subjects found this time in an earlier and simpler world. I can only recommend people who care for imaginative writing to get this book, and allow the author to show them what he has described in the world of primitive humanity, whatever be its date, and how it can be interpreted by a poet in terms of beauty.

R. M. DAWKINS.

A POSTSCRIPT TO DARWIN'S "FORMATION OF VEGETABLE MOULD THROUGH THE ACTION OF WORMS"

By SIR ARTHUR KEITH, F.R.S.

ON December 20, 1842, three months after taking up residence at Downe, Darwin spread "a quantity of broken chalk over a part of a field near my house" with a view "of observing at some future period to what depth it would become buried". Twenty-nine years later—1871—he had a trench dug across this part of the field; "a line of white nodules could be traced on both sides of the trench at a depth of 7 inches from the surface. . . . Another part of this same field was mossy and it was thought that sifted coal cinders would improve the pasture, a thick layer was spread over this part either in 1842 or 1843, and another layer some years afterwards". In 1871 a trench was dug revealing a line of cinders at a depth of 7 inches and another parallel line at 5½ inches". (These citations are taken from pp. 139, 141 of the 1881 edition of Darwin's book, "The Formation of Vegetable Mould through the Action of Worms"; in the remainder of this article, I shall cite merely the page number. Darwin began observations on the formation of mould in 1837 while staying at Maer, Staffs, the home of Josiah Wedgwood—his uncle (and future father-in-law). His observations of that period were communicated to the Geological Society of London on November 1, 1837.)



A PLAN OF DARWIN'S MEADOWS WITH SITES AT WHICH SOUNDINGS WERE MADE.

A B. North meadow; the sites of trenches are numbered *a–r*.

C. Middle meadow; *D*. South meadow or cricket field. The sites at which chalk was found are marked by black circles, those in which chalk was absent by open circles.

E. "Little Canada".

SW. Sandwalk.

FF. Great Pucklands. *LP*. Little Pucklands.

CP. Chicory patch.

Other explanations in text.

Anyone who is interested in Darwin's experiment and who wishes to ascertain what has become of his line of chalk nodules and of sifted coal cinders after the lapse of a century is met at the threshold of his inquiries by the fact that Darwin gives no indication of the part of the field on which chalk and cinders were spread, nor are we certain of how much he included under the term 'field'. At present the twelve acres (Ordnance Survey gives 14·4 as the acreage of Darwin's field) of pasture land which was purchased with Down House* is divided into three meadows (see accompanying figure)—a north meadow (*AB*) near Down House, a small middle meadow (*C*) and a distant or south meadow (*D*) now used as a cricket field. The sandwalk (*SW*) which bounds these meadows on the west was acquired from Sir John Lubbock at a later date. The pasture land was so divided during Darwin's lifetime, but when he speaks of a "field", apparently he does not refer to a meadow but to the whole of the twelve acres. Major Leonard Darwin agrees in this interpretation and cites the following passage from "Life and Letters of Charles Darwin" written by his brother Francis: "Eighteen acres of land were sold with the house, of which 12 acres on the south side of the house form a pleasant field" (vol. 1, p. 321). In writing to his sister Susan in 1845, Darwin mentions a mound which hid "part of the field". Yet on p. 298 of his work on the formation of mould we have this passage: "It may be well to recall here the case of fragments of chalk buried beneath worm-castings on one of my fields."

Even if we agree that Darwin included all twelve acres under the term "my field", we have still to discover the parts on which he spread chalk in one case and sifted cinders in another. Major Leonard Darwin, on my appealing to him, thought the most likely area to receive an application of cinders would be that part of the north field (*A*) lying adjacent to the house—the north-east corner—and it is in this area that my trenches reveal the cinder-layer at its thickest; but cinders, fragments of unburned coal, of brick and of tile were found throughout the twelve acres—all at the same uniform depths. Chalk was found nowhere in fields *A*, *B*, with the exception of one small pocket to be mentioned later. It was found in that part of the cricket field lying by the side of the sandwalk and in the adjacent field *C*—an area less than an acre in extent. Major Darwin had no direct knowledge of the site when I informed him of my discovery of chalk nodules in the cricket field; he wrote: "Memory plays me many tricks, but I now have an idea or memory that chalk was put on the field near the sandwalk because it was felt it would look ugly near the house."

---

* "Downe" is the spelling given by the Ordinance Survey for parish and village; "Down" is the spelling used by the Darwins for their home.

Before proceeding to describe what was revealed by my trial trenches in Darwin's field let me turn for a moment to an eleven-acre field which bounds the Darwinian property on the west (*FF*). It was in the first stage of becoming pasture land when Darwin arrived in 1842, having been last ploughed in 1841, and has remained in pasture ever since. The larger part of this field is on the flat upland, but its western part slopes rapidly down over the brow of an adjacent valley or coombe. "The field," writes Darwin, "was always called by my sons *the stony field*. When they ran down the slope the stones clattered together. I remember doubting whether I should live to see these larger flints covered with vegetable mould and turf. But the smaller stones disappeared before many years elapsed, as did every one of the larger ones after a time; so that after thirty years (1871) a horse could gallop over the compact turf from one end of the field to the other and not strike a single stone with his shoes."

The local name for the stony field is Great Pucklands. In 1931, three years after he had purchased Darwin's home and grounds, repaired and endowed them and transferred them as a trust to the British Association, Sir Buckston Browne bought Great Pucklands and the adjacent Little Pucklands and gave them to the Royal College of Surgeons of England as a site for a station or farm for surgical research, which was also endowed by his munificence. Thus it was I came to make my home in Downe and to make an acquaintance with Darwin's "stony field" and ultimately to wage war upon its weeds.

At the beginning of 1941, Dr. Colbeck and I, being in need of winter fodder for the College guinea pigs, ploughed half an acre of Great Pucklands to a depth of six inches and sowed out in chicory and kale. In the spring of the present year (1942) the kale having been uprooted and the chicory blades having died down, this half-acre presented the stony appearance that had met Darwin's eye over the whole of Great Pucklands a century before. I marked out half-a-square yard (36 in. by 18 in.) between two of the chicory rows; loose flints on the surface numbered 137, weighing collectively 14 lb.; I sifted the soil underneath down to a depth of 8 in. and obtained more than four hundred flints (varying in weight from 15 gm. to 450 gm.) and weighing collectively 39 lb. Thus in every square yard down to a depth of 8 in. there were 106 lb. of flints, amounting in round numbers to 230 tons per acre. The re-assortment of soil and flints, effected by worms in Great Pucklands during the past century was revealed by sections made in various parts of the field both on the level and on the slope.

Let me first compare the section which Darwin made in 1871 with one I have just dug at or near Darwin's site (*PA*). His section revealed (p. 144) an upper stratum, rather less than three inches in thickness, of stone-free mould (including turf) and a lower stratum which he described as "a coarse clayey earth full of flints". While the evidence from his own fields indicated that worms threw up mould at the rate of an inch in five years, here the evidence was of a much slower rate, namely, an inch in twelve years. My section showed the same thickness of stone-free mould as did Darwin's. In my section it varied from 2·5 to 3 in.; under the mould came a "stony stratum" 5 in. in thickness and containing more than one thousand flints, similar in size to those met with in the chicory patch, the stones being held together by Darwin's "coarse clayey earth". In all sections of our turf-land over the chalk this "stony stratum" serves as a bench-mark, particularly its uppermost stones, which form a kind of pavement. Under the stony stratum, beginning at a depth of 8 in., came weathered clay with numerous flints, which I dug to a depth of 15 in. from the surface without finding any object foreign to the clay.

Thus it will be seen that in the seventy-one years which have come and gone since Darwin made his record the surface strata on the declivity of Great Pucklands have remained in a state of equilibrium. Some of the factors which help to maintain a stationary position in spite of worm action, or rather because of it, are suggested by other sections I made along the valley-set part of Pucklands. Some thirty yards farther down the slope than the trench just described (*P B*), the field ends on the side of the valley in a steep bank, occupied by a belt of ancient beech trees. As the bank is approached the land becomes nearly level. Rank grass grows here which every autumn becomes cluttered with brown beech leaves—food for the worms. Here I expected to find the soil deep, and that I think would have been Darwin's expectation. To my surprise my spade struck the stony stratum before it was three inches into the turf. The mould was intensely black in colour, very friable, and was 2½–3 in. in thickness. The underlying stony stratum was 6 in. in thickness and, again to my surprise, the clay under the stony stratum was white with chalk nodules, the chalk being 3 in. under the stony stratum and continuing to a depth of 14 in.—beyond which I did not dig. The earth between the flints of the stony stratum was very black and had in it much decayed fibrous material; there was ample evidence of worm action in the stony stratum and in the overlying mould but none in the chalk. Darwin must have known that a stratum of chalk serves as an efficient worm barrier. Under the walk of his kitchen garden there are 8 in. of chalk, which although laid down in 1845, still keeps worms from reaching the gravelled surface. When he laid down the "sandwalk" he used chalk as a foundation. So with the trench just described; the underlying chalk seems to limit the traffic of worms in a downward direction. I ought not to have been surprised at finding chalk in the depth of this trench, for along the side of the coombe, at the level of the beech bank, is a series of disused chalk pits.

Other trenches dug into the more level ground, above the beech bank and about a hundred yards to the west of the one just described (*PC*, *PD*, *PE*), throw light upon the manner in which the stony stratum, in a long-established pasture, is maintained at a fairly constant level. The trench I am now to describe lies in the middle of the zone which becomes so thickly covered with beech leaves every autumn and from which they vanish in early summer. There were ample signs of worm casts at the site; I counted eight fresh ones in an area of two square feet and as I cut the turf counted eight worms. The surface mould was black as soot but only 2½–3 in. in depth. The stony stratum, 4 in. in thickness, contained black sandy earth with black vegetable fibre; below the stony stratum came a fine sandy loam with a line of chalk nodules in it, three inches below the stony stratum. While the mould was black the underlying loam was snuff-coloured, so that any mixing of the black mould with the underlying loam was easily detected. It was clear that the worms were conducting a double-way traffic; the black-coloured mould carried into the deeper loam seemed to me to exceed the amount of loam added to the black soil. If the loam brought above the stony stratum by worms is equal to the mould which they and the rain carry through the stony stratum, then a condition of equilibrium would be attained.

So far I have been dealing with sections made on the sloping parts of Great Pucklands; but before returning to Darwin's own field it will be helpful to examine a typical section made through the turf on the flat area of Pucklands. Here, as in Darwin's field, the surface soil is separated from the underlying chalk by a red clay varying from 8 to 14 ft. in thickness and containing numerous flints. The section I shall describe is one made about 120 yards to the east and south of the chicory patch (*P F*). In my earlier trenches I first removed the turf with 2 in. of soil from an area measuring 36 in. by 18 in. (half a square yard) and then deepened this area, 2 in. at a time, until a depth of 14 in. was reached. The material from each 2-in. level was sifted, the contents of my sieve being noted for each level—flints, pebbles, brick, tile, cinder, charcoal, iron, etc. I took my levels from a straight edge laid across the trench resting for 6 in. on the more level and shorter turf on each side of the trench.

After a time, finding the soil structure to be uniform throughout the level pasturage of this neighbourhood, I replaced this tedious method by a simpler one which I shall now illustrate in connexion with the trench I am to describe—that to the south-east of the chicory patch (*CP*). My spade, a light one with straight blade, 6 in. wide and 9½ in. in depth, sinks easily through the short turf and grates against the stony stratum at a depth of 4 in. or 4½ in. A little movement of the handle causes the turf, and soil under it, to separate from the stony stratum, where the roots of the herbage end, only the deeper rooted weeds—the dock, thistle, knapweek, etc., penetrating the stony stratum to the subsoil of weathered clay (often sandy) underneath. In the chicory patch the flints were intermingled with the soil; but here the worms have thrown the soil up and permitted flints and all foreign bodies which may happen to have been present in the soil at the time of ploughing, cinders, bits of tile and brick, etc., to subside into the stony stratum. Anything thrown on the turf later will be arrested in its submergence when it reaches the stony stratum. Any foreign body found under the stony stratum was probably *in situ* before the stony stratum came into being. The turf, with the underlying mould, as I have said, separates easily and naturally from the stony stratum. When we turn its deeper surface up to the light, we find the openings of worm burrows, a few of the worms and some of the looser small flints which have come away from the stony stratum with the turf. In this particular trench (*P F*), I was surprised by a complete absence from the deep aspect of the turf of small pebbles, cinders, fragments of brick, etc., which are so abundant at this level in the neighbouring Darwinian fields. The removal of the layer of turf exposes the upper aspect or pavement of the stony stratum—the chief level of worm activity and of mole activity. Worm chambers were noted here but only two polished pebbles; usually there are a dozen of such pebbles, smooth and glistening, apparently from the friction of worm movement. The stony stratum was made up of flints of the same size and number as were loosely strewn through the soil of the chicory patch. I dug to a depth of 14 in. from the surface—that is 5½ in., into the weathered clay under the stony stratum—but found only virgin ground. There was no trace of chalk to be seen.

With the experience of Great Pucklands to fortify us, we are now to make a survey of Darwin's meadows beginning with a triangular enclosure about half an acre in extent known in recent days as "Little Canada" (*E*); it is at the southernmost extremity of Darwin's land, beyond the cricket field. It had been a vegetable garden but twenty years ago it was left at the disposal of Dame Nature, who made it into a wilderness of thorn, blackberry, wild-rose, traveller's joy, with an abundance of thistle and nettle. In January of the present year (1942) with Dr. Howarth's consent, I began its clearance, but after the clearance and before ploughing, made an examination of the soil structure, similar to that made in the chicory patch. In twenty years, worms had covered the larger more superficial flints with a layer of black mould less than half an inch in thickness (1 cm.); between these superficial stones the mould was about 3 cm. thick—perhaps 1½ in. Darwin knew that worm castings accumulate very slowly on the surface of ploughed land but gave no explanation. There is no lack of worms in "Little Canada"; in the loosely knit upper soil they seem to be able to get rid of their castings without actually emerging on the surface—as they have to do when the soil is covered by dense turf.

I dug a trench of the usual size (36 in. by 18 in.) down to a depth of 15 in., sifting each level as I deepened my trench. I found, but not clearly defined, three strata; the uppermost ended at a depth of 2 in., which I shall label *A*; below *A*, came *B*, three inches in thickness (3rd, 4th and 5th inches); and deepest of all *C*, extending from the 5th to the 15th inch. There were two levels or zones at which foreign material had accumulated—namely, in *B* (which represents an initial stage in the formation of a stony stratum); in this there were many fragments of unburned coal, cinders, pieces of brick, fragments of pottery; the second foreign zone was in *C*, namely, between the 8th and 10th inch. At this level in *C* occurred fragments of coal and of charred wood, pieces of brick and seven nodules of chalk (at the 10th inch level). The flints in the upper stratum (*A*) numbered 138, in *B* 353, in *C* 550.

We now enter the "cricket field" in search of the site of Darwin's experiment with chalk chips and bend our steps to that part which adjoins the sandwalk. Here the zone of the field which adjoins the sandwalk, about twenty yards in width, is now, and has been for many years, undermined by moles. On and near their 'heaps', in one particular part, lying near where a gate enters from the sandwalk—towards the north-west corner of the field—there are many fragments of chalk. Chalk does not occur in earth thrown up by moles in any other of Darwin's meadows. My trenches in the bigger field (*A*,*B*) uncovered not a single nodule of chalk; only in a zone adjoining the sandwalk did my trenches reveal chalk with any degree of constancy; and even here there was no certainty; a trench might reveal an abundance and the next trench dug within the chalk area and within a few yards of the first yield not a trace.

The area on which Darwin spread chalk was apparently a zone of the cricket field adjoining the area which later became the sandwalk, about 25 yards in width and extending from one side of the cricket field to the other—about a hundred yards in extent. The chalk zone continues into the adjoining or mid-field, ceasing when the northern boundary of that field is reached. In the sketch map the soundings which yielded chalk are indicated by black circles, those which were free from chalk are indicated by open circles. The trenches which reveal chalk are most thickly grouped on the border of the sandwalk; the chalk area is rather less than an acre in extent. In this area chalk occurs at four levels: (1) on the surface thrown up on mole hills; (2) in the mould at a depth of 3–5 in.; this I regard as chalk which had been thrown on the surface by moles at some time within the last twenty years. It occurred at this level in nine of the fifty-five holes I dug in fields *C D*. The third level at which chalk occurs is that at which Darwin found it in 1871, namely, 7 in. I infer Darwin measured to the deepest point of the chalk level, the nodules thus occupying the whole depth of the 7th inch. Now this level lies invariably within the "stony stratum" which usually begins at 4–4½ in. from the surface and extends to a depth of 8–8½ in., at which level the subsoil of weathered clay or sandy loam begins. In only nine of the fifty-five holes dug was chalk found at the Darwinian level. If the chalk I have found at the 7-in. level is a remnant of Darwin's spreading, as I believe it to be, then there has been no movement since 1871. The fourth chalk-level is 3–4 in. under the stony stratum, embedded as big nodules in the soft clayey-loam, occupying a very definite and regular zone. This was by far the most constant level at which I found chalk. In the thirty-four soundings which yielded chalk in fields *C* and *D* the chalk occurred at this deepest level, namely, 9–12 in. beneath the surface in twenty-five instances.

Does this deep chalk represent a remnant of that spread by Darwin in 1842? I am convinced, for various reasons, that it does not, but had been at the level we now find it long before Darwin's time. Darwin was confident that his field had been in pasture for at least thirty years before he came to Downe—probably, he adds, for "three times thirty years". We may be certain that a stationary stony stratum was already in existence long before 1842. Could the chalk nodules penetrate this stratum and so reach the subsoil? Let me quote Darwin's actual words touching this point (p. 140): "Beneath the line of chalk nodules there was in parts hardly any fine earth free of flints, while in other parts there was a layer, 2½ in. in thickness. In this latter case the mould was altogether 9¼ in. thick; *and in one such spot a nodule of chalk and a smooth flint pebble, both of which must have been left at some former time on the surface, were found at this depth*". I have italicized part of the last sentence, for Darwin, too, was apparently suspicious of the deep chalk as being of his sowing. I have seen 'break throughs' in the stony stratum; they are rare; the stratum is usually intact and the chalk nodules in the subsoil are regular—not haphazard in their disposition. Chalk also occurs outside the 'chalk zone'—in the eastern part of field *C* and in the adjoining part of the cricket field. Here it occurs at the deepest level.

What I have observed in nowise invalidates Darwin's experiment. He spread chalk on the turf and in twenty-nine years found that it had become buried by worm action to a depth of 7 in. Under the dissolving action of rain, of root action and of organic acids in the soil, angular pieces had become reduced to rounded nodules. In the seventy-one years that have come and gone since he examined his line of chalk nodules exposed in section, the solvent action of rain, of root and of soil continued on the chalk nodules and only traces of his experiment are now to be found. But the deep chalk which was *in situ* before the field was last ploughed, perhaps a century before Darwin's day, is protected from these agencies by its depth and still survives as nodules of considerable size (30 mm. by 30 mm. by 20 mm.).

The part of the field which was 'mossy' and over which a thick layer of "sifted coal cinders" was spread, I believe to have been, as Major Darwin suggested, that area of the north meadow (*A*) which lies adjacent to Darwin's house and lawn. Every one of the twenty soundings I made in the north meadow (*A B*) revealed a line of cinders in or near the 6th inch, counting from the surface, but the cinder layer in the area lying towards the house was much richer and thicker than elsewhere.

As already explained I dug my earlier trenches, spit by spit, sifting each as my trench deepened. We may take the results from a trench dug in meadow *A*, within fifty yards of Down House, as representative of the richer area. The vegetable mould, sifted down to a depth of 4½ in. left in my sieve nine small flints, four pebbles, two cinders; the next spit, down to a depth of 6½ in., thus including the upper level of the stony stratum, eighty flints, large and small, forty-eight pebbles, ninety-five cinders (including among these many fragments of uncharred hard coal or anthracite), four fragments of brick and several other foreign bodies; the third spit, down to a depth of 8 in., thus including the rest of the stony stratum, gave 328 flints, forty-four pebbles and only four cinders. Deeper than 8 in. no foreign object was found in this trench, but in others pieces of brick and tile were frequently observed. Indeed it may be said that fragments of brick and tile are to be found everywhere in Darwin's meadows, both in the upper and lower levels.

When, in 1871, Darwin dug a trench he observed "many cinders lay in a line at a depth of 7 inches from the surface". Here, as in the case of his line of chalk nodules, I infer his measurement refers to the deepest point reached by the cinders. In the seventy-one years which have elapsed since Darwin made his sounding, although worms have been throwing up castings every year, the cinder layer has certainly not become deepened in its level. Having subsided, under worm action, to the bottom of the vegetable mould, cinders and all foreign objects become arrested on and between the upper flints of the stony stratum and there remain until they are dissolved by soil agencies. Indeed my data indicate that the thickness of the vegetable mould in Darwin's meadows has diminished to an extent of half an inch, perhaps a whole inch. More has been washed out, or taken out of the soil, than has been returned to it. There has been much and prolonged hard farming.

I was able to verify and extend another of Darwin's observations recorded in the following passage (p. 141): "In another part of this field, which had formerly existed as a separate one" (see *B*) "which it is believed had been pasture land for more than a century, trenches were dug to see how thick the vegetable mould was. By chance the first trench was made at a spot where, at some former period, certainly more than forty years before, a large hole had been filled up with coarse red clay, flints, fragments of chalk and gravel ; and here the fine vegetable mould was from $4\frac{1}{8}$ to $4\frac{3}{8}$ in thickness". In a corner of field *B*, situated at the north end of the sandwalk, there is still to be seen a wide hollow, which, before it was filled up, had perhaps served as a cattle pond (*p.q*). Digging here, where grass grows rank and strong, I found the vegetable mould measured $3\frac{1}{2}$ –$4\frac{1}{2}$ in. ; under it came a thick stratum of flints and at a depth of $8\frac{1}{2}$ in. below the surface, several large blocks of chalk but I failed to find the coarse red clay. This, however, I found in an adjacent hollow of the neighbouring field (*s* in *C*). In this neighbouring site the mould, which is very black, for the hollow is shaded by trees of the sandwalk, measures only 2–3 in. in thickness and showed much evidence of worm activity. The black mould rested directly on a red plastic clay, which yielded to the spade as if it were cheese. In the red clay could be seen long 'test-tubes' or fingers of black mould which worms had carried from the shallow surface layer into the cheesy red-clay. The worm castings were black ; none were red. Thus it will be seen that the vegetable mould covering the sites of two former holes at the northern end of the sandwalk, remain much as they were in Darwin's time. The mould has not increased in the past seventy-one years ; such slight evidence as there is points rather to a diminution in thickness.

Perhaps readers may recall the passage (p. 145) in which Darwin gives an account of a "narrow path running across my lawn, paved in 1842 with small flag-stones set on edge ; but worms threw up many castings and weeds grew thick between them. . . . The path soon became almost covered up, and after several years no trace of it was left". In 1877 Darwin removed the turf and found the path "covered by an inch of fine mould". One would like to know how deep that path now lies in Darwin's lawn but Dr. Howarth and I have 'sounded' and searched for it in vain. But I suspect it is covered by at least 5 in. of mould, for the fork I used in my soundings had prongs of that length.

Summary. I have given in this article an account of the chief facts revealed by digging trenches, some seventy in number, in the fields at Downe, which supplied Darwin with so much of his data for his work on "The Formation of Vegetable Mould through the Action of Worms". The main result is to prove that after a time chalk, cinders or other foreign bodies, when spread on the turf, do not continue to be buried deeper and deeper by worm action, but reach a stationary level. This is due to the fact that, in the fields at Downe, the action of worms is twofold ; they throw up on the surface a stone-free vegetable mould ; they cause flints and all solid objects in the soil to subside into a stony stratum. When objects have reached the stony stratum they remain stationary. When a stone is thrown in a pond it sinks to the bottom and there remains ; it is the same if we cast an object upon permanent turf ; under the action of worms it sinks to the bottom—the stony stratum and there abides. Plentiful remains were found of the cinders spread by Darwin a century ago ; but his chalk chips have almost disappeared. Objects found in the subsoil under the stony stratum are survivals from the period which preceded the last ploughing.

BIOLOGICAL ASSAY OF INSECTICIDAL SPRAYS

By DR. E. A. PARKIN
Pest Infestation Laboratory, Department of Scientific and Industrial Research

MORE than a hundred and fifty different kinds of insects have been found from time to time on stored produce, but only a dozen or so are found often and in dangerous numbers. The control of these insects is a matter of considerable economic importance, more particularly when foodstuffs susceptible to attack by them are kept in store over prolonged periods and wastage must be avoided. The use of insecticidal sprays as a control measure, in warehouses where grain, dried fruits, cacao, etc., are stored, is comparatively simple and, when properly applied, has been shown by experience to be effective, provided the infestation has not been allowed to reach too great proportions. The Pest Infestation Laboratory of the Department of Scientific and Industrial Research is therefore carrying out a study of these insecticidal sprays as one of the chief items in its programme of research on ways of combating infestation of stored produce by insects. Special attention has been given to the development of a method of comparing the killing power of different sprays since it was evident that a comparative test of this kind was essential as the next step in the process of improving insecticidal sprays. The technique of the test which has been successfully worked out at the Pest Infestation Laboratory is described in the second half of this article.

As a control measure spraying has the advantage of being simple and safe to both operator and goods, if done with reasonable care. The chief requirements of an insecticidal spray are that : (1) it should be toxic to as many of the common pests of produce as possible, in the concentrations which can be economically applied ; (2) it should retain that toxicity as long as possible after it has been applied ; (3) it should not be toxic to man ; (4) it should not taint goods to which it may be applied ; and (5) it should not be inflammable. A spray may kill insects by direct contact, by leaving a toxic film on surfaces, or by evaporating to give a poisonous vapour, thus acting as a local fumigant.

The first scientific study of the use of a pyrethrum–oil mixture as a spray for controlling infestation in warehouses was carried out for the Australian Dried Fruits Board by the Department of Zoology and Applied Entomology of the Imperial College of Science and Technology under Prof. J. W. Munro between 1931 and 1938. This is described in two papers by Dr. C. Potter[1]. This work was designed to develop a method of controlling the infestation of dried fruit in warehouses by the moths *Plodia interpunctella* Hb. and *Ephestia elutella* Hb. At first, the technique consisted of filling the warehouse with a finely atomized mist of a mixture of pyrethrum extract in a heavy, highly refined white oil. This process was carried out every evening during the period of emergence of the moths. Although this was found to be effective, it was expensive in labour and materials, involving a lengthy spraying process every day for a period of at least three months. It was found later that the effectiveness of the pyrethrum–oil spray was largely due to the fact that, when it settled, or was sprayed directly on to a surface, it left a film which remained toxic to moths and caterpillars for some days. A concentration of 1·6 per cent weight in volume of pyrethrins I and II was at first used in the mixture, but experiments showed that a concentration of 0·8 per cent was sufficient for these two moths in all stages of their development. The new technique of spraying the walls of the warehouse and the boxes of goods stored in it twice a week from the middle of May until the end of September, was extensively used in London, Liverpool, Glasgow, Manchester and elsewhere and proved effective, while being cheaper and simpler than the technique first used.

This experience naturally led to the use of this spray as a control measure against other insects of stored produce, including the coleopterous pests of grain, flour, etc., which are more resistant to insecticides. It was found by practical use that a spray containing 1·6 per cent total pyrethrins gave a good measure of control, though there was no means of testing accurately the effectiveness of sprays of different concentrations.

This mixture of pyrethrum extract in oil was selected as being the most suitable type of insecticidal spray for warehouse use of which both the constitution and the performance were well known. Attempts to improve it are, however, being made in the light of practical experience of its use and of fundamental biological research on the insect cuticle, now being carried out in the Imperial College of Science and Technology by Dr. Hurst[2]. These attempts are directed towards the search for substitutes for pyrethrum as the toxic principle of the spray, and towards the search for activators which, when added to the simple pyrethrum – oil mixture, will increase its toxicity to insects. Such attempts are prompted both by a desire to improve the sprays themselves, and also to effect economies in the use of pyrethrum, which has to be imported, chiefly from Kenya, at the present time.

If insecticides contain only pyrethrum in the specified oil, the maintenance of a standard of toxicity can be achieved by chemical determination of the pyrethrum content, but to compare the effectiveness of sprays containing activators, or toxic principles other than pyrethrum, with such a simple spray, it is clear that a biological assay is required.

A committee, under the chairmanship of Dr. F. Tattersfield of the Rothamsted Experimental Station, recently considered the specification of a standard spray and the methods of assaying sprays for use against the insects of stored produce. A specification of a standard spray was drawn up by Prof. J. W. Munro (Imperial College of Science and Technology) and Mr. J. C. F. Fryer (Ministry of Agriculture, Plant Pathological Laboratory). This is a mixture of an extract of pyrethrum in heavy oil with a similar heavy oil diluent to give a final concentration of 0·8 per cent (wt./vol.) pyrethrin I, equivalent to a concentration of about 1·6 per cent total pyrethrins. The specific gravity, viscosity, unsulphonatable residue and flash point of the oil have been specified, but it is realized that in present circumstances it may not be possible always to obtain an oil corresponding exactly to that recommended. The determination of the pyrethrin content should be made by the method of Wilcoxon and Holoday as modified by Dr. J. T. Martin (Rothamsted Experimental Station) and Mr. S. Brightwell (Imperial Institute). As a stabilizer it is recommenced that 2·5 per cent by volume of a 10 per cent solution (w./v.) of pyrocatechol in ether be added to the mixture.

The Committee accepted this specification as a standard insecticidal spray and emphasized the need for a biological test for comparing other sprays with it. At the Committee's suggestion, the development of such a test of the insecticidal power of a spray was undertaken at the Pest Infestation Laboratory of the Department of Scientific and Industrial Research. It was decided to concentrate attention first on the film effect as being the most important for the purpose for which the sprays would be used, although, for a complete comparison, the effect of direct spraying and any fumigant action would also need to be measured by independent methods. With the knowledge which has been gained in devising the film test, however, the establishment of suitable techniques for evaluating the spray and fumigant effects should not be difficult.

The test of the film effect of an insecticidal spray consists essentially of the exposure of a number of insects, bred and handled under standard conditions, on a surface to which has been applied a measured quantity of insecticide. The number of insects dead after a given time is counted and the results are analysed statistically.

The test insects are flour beetles, *Tribolium castaneum* Hb., bred on wholemeal flour protected from infestation by mites and kept under standardized and controlled conditions at 24° C. and 70 per cent relative humidity. The beetles are tested when they are 3–5 weeks old. Careful organization is necessary to ensure a steady supply of insects for test. A spraying tower designed by Dr. Potter[3] is used to apply the insecticide, which is atomized through a nozzle at the top of the tower by air at a pressure of 15 cm. of mercury. The selection of a suitable substrate on which to deposit the insecticide caused some difficulty, but after a number of materials had been tried, Whatman No. 544 filter paper was found to be the most satisfactory. A range of deposits is chosen to cause mortalities of 30–90 per cent after both 6 and 9 days exposure. With the *T. castaneum* stocks in use at present at the Pest Infestation Laboratory a range of deposits of the standard spray (0·8 per cent pyrethrin I) from about 1·55 to 2·62 mgm. per sq. cm. are needed. This range is covered by spraying six or seven papers with increasing deposits, but two to three additional deposits of about 2·0 mgm. per sq. cm. are made to fix with greater certainty the position of the regression line in the region of 50 per cent kill. Fifty beetles are placed on each of the sprayed papers and confined by a glass ring 6 cm. in diameter. The exposure is made in the dark at 24° C. and 70 per cent relative humidity. Controls are also kept, in similar conditions, on untreated paper. The dead insects, that is, those showing no spontaneous movement even when lightly pressed on the metasternum, are counted after 6 and 9 days.

The influence of several factors on the homogeneity of the results has been investigated. In particular, the importance has been shown of allowing beetles time to recover from the mechanical shock inherent in the method of counting into batches. It has been found necessary to pay special attention to the cleanliness of all jars, plates and rings used, freeing them from traces of alkali, which is liable to remain after washing in soapy water, and protecting them, and especially jars containing insects awaiting exposure, from drifting mist of insecticide in the spraying laboratory.

Comparison of insecticides should be made on the results of the nine days count, unless there is reason to suppose that the figures for six days would be more reliable. The data, representing observed mortalities between 30 per cent and 90 per cent for known deposits of insecticide, are analysed statistically by the method described by Bliss[4]. Data obtained from a film test, as described above, should be homogeneous with respect to goodness of fit to the provisional regression line. When two insecticides are being compared, agreement in position and slope of their regression lines may be compared by the direct χ^2 test given by Bliss. If the data are heterogeneous and it is desired to proceed with the comparison, the '*t*' test should be used.

Experiments have shown that this technique will clearly distinguish a standard type of insecticide containing 0·8 per cent pyrethrin I from a similar spray containing 0·65 per cent. In most instances the test will distinguish 0·7 per cent from 0·8 per cent, and 0·7 per cent should ultimately become the reliable limit. Such a limit is considered satisfactory for the purposes to which it is intended to apply this test and it is doubtful whether the method could be made to work within closer limits except, perhaps, after a detailed investigation which is unwarranted in the present circumstances.

It is proposed to apply the test to the comparison of new sprays with the standard as the study of insecticidal materials brings to light substances worthy of trial. It will also be used to select the most suitable of the existing sprays for use in the different conditions which arise in practical pest control in industry.

A full account of the development of this test is being prepared for publication.

SCIENCE AND PRACTICE IN AGRICULTURE

So long as farming was a cycle of routine operations conducted at what we should now call a low-level production, there was little need for any technical knowledge beyond that derived from a thorough farm training in the local husbandry. When the production of crops and stock came under scientific examination rather more than a century ago, the clearer understanding of the principles involved in farming operations began to make technical advances possible. Some of them, such as the introduction of artificial fertilizers, were advances of the first magnitude, and presented completely new possibilities to the farming community. There then developed a need which has lost none of its urgency in spite of all the efforts made to meet it: How are we to bridge the gap between the laboratory and the field, between the man of science who provides the key to improved methods of production, and the farmer whose business it is to put them into successful operation? In the early years this task fell to the few agricultural societies with their old-established journals, the research stations being represented only by Rothamsted, and the colleges only by the Royal Agricultural College at Cirencester. Gradually the organization of agricultural research and education was built up into the form we know to-day. This organization has done excellent work, but agriculture in Great Britain is now faced with the biggest task in its history, and the success achieved will largely depend on the extent to which existing knowledge and new developments can be presented to ordinary farmers in a way that will gain their confidence and prompt acceptance.

This subject, under the title of "The Better Dissemination of Scientific Knowledge among British Farmers", formed the basis of a discussion recently held by the Parliamentary and Scientific Committee. Most of those taking part spoke with the authority derived from a life-long experience of agricultural research and farming affairs, and the proceedings served to bring out clearly the essential points of the problem.

The results of scientific research will only appeal to farmers if they bear clearly and directly on current agricultural questions. This in itself presents a difficulty because research is necessarily slow, and in so far as it involves field trials, its pace cannot be increased. Consequently the scientific workers must have long notice of problems which will sooner or later begin to attract the anxious interest of the farming community. When the country's agricultural policy is vague and in a state of improvisation, as it has been in the period between the War of 1914–18 and the present War, the planning of research is difficult. A well-defined agricultural system brings out the important problems more clearly, and the fact that they are being studied leads to close co-operation between research and advisory workers and the farmers. This tendency is seen, for example, in such places as New Zealand and Denmark, where an important part of the farming is devoted almost exclusively to the production of a standard product for the export market.

In Great Britain a settled agricultural policy would be of the greatest assistance to research workers, advisory staffs and the farming community. There are naturally many forms that such a policy might take, but one of the most attractive was advocated in the discussion by Sir John Russell, when he pointed out that a plan for farming based on the nutritional needs of the country would provide very favourable conditions for agricultural research and the ready application of its results to current problems.

In order fully to exploit new technical advances, there must be a certain elasticity and receptivity of mind on the part of the farming community. All were agreed that the time to develop this is in early life. Improved general education followed by vocational training should help greatly here, together with the Young Farmers' Clubs with their wisely chosen programmes of practical work, judgment, and discussion. Deep technical knowledge is scarcely essential at this stage, though facilities exist in the university departments of agriculture for those who want to specialize; rather should the young farmer know in a general way what type of technical information is available and where to go for it. This is not to underrate the value of a scientific background. In a written communication, Dr. W. K. Slater pointed out that a change in methods may be undertaken more readily if the underlying reasons are understood. A full explanation of a new system, going right down to scientific principles, is sometimes the best method of approach.

The best method of presenting agricultural information and advice is almost always by a personal visit of the advisor to the farmer. In this way the transaction acquires a directness and intimacy that no other means can approach. Objections and questions can be dealt with immediately and all relevant information is normally accessible. But the personnel of this advisory service is regarded as highly important. The research worker himself may not be the best man for the job ; indeed it is seldom that the scientific worker has had the time or opportunity to acquire that thorough first-hand experience of the land which counts so much in farming circles. The type of man chosen for this work should therefore be perfectly sound on the practical side, with sufficient experience of management to be able to regard a proposed course of action from the farmer's point of view. He must also have enough scientific knowledge to understand the work of the research department and explain its more practical aspects to those who would have to apply them.

Next in importance comes the demonstration farm, where technical improvements may be seen in operation alongside the older methods. The effect is often convincing, but the improvement must always be regarded in its agricultural context, and may have to be modified under expert guidance to suit some local set of conditions. This method is being used with considerable effect by the County War Agricultural Committees, who have set themselves the task of putting up straightforward illustrations of improved methods throughout their areas. A demonstration by itself can seldom be entirely satisfactory ; it should have competent demonstrators, and the resulting informal discussions on the headland of the field provide perhaps the most convincing type of farmers' lecture.

Farmers are not great readers ; certainly not of the more scientific journals or even of the popular expositions of agricultural research. The limited number who are in close touch with science and education or are active supporters of the leading agricultural societies are in no way typical of the general body. For wide consumption accounts of new methods must be written in a very direct style shorn of scientific technicalities. Official bulletins, the weekly agricultural Press and, in expert hands, the local Press, can do good work in this direction. Farmers should feel, however, that they have always some specialist within reach who would discuss and amplify information derived from these sources.

In most matters relating to British agriculture the tendency is to make comparisons, sometimes rather unfavourable, with the achievements of the Dominions or foreign countries. Lord Bledisloe, in his opening survey of the position of agricultural research and advisory work in the many countries of which he has had first-hand knowledge, certainly gave the impression that, on the whole, agricultural information is more widely disseminated and more readily received elsewhere than it is in Great Britain. Some of the reasons for this, such as a more fixed agricultural policy and more general technical education, have already been mentioned. In addition, in many countries agriculture has been a much more vital concern than in Great Britain before the War, and, in the Dominions at any rate, the race of farmers have a shorter background of traditional methods, and consequently feel less settled in their ways. Most of the methods of disseminating knowledge used elsewhere appear to have their close counterparts here, although it is possible that in Great Britain they may be handled with less vigour and effect. It was pointed out that our agricultural education, being planned on a county basis, is often uneven in quality, the wealthier and possibly less agricultural counties being in a position to spend more than the others. There is room here for some form of central finance and direction that will make for a more uniform standard. This point was elaborated by Dr. Slater, who suggested that there should be one national service for the dissemination of scientific information under a technically trained director who would control both the advisory and the county staffs, maintaining the scientific standard of the former and the quality of the instruction given by the latter. He would foster collaboration between the two branches, and maintain close contact with the research institutes. Because a system is successful abroad it by no means follows that it is best for British conditions ; nevertheless, the feeling was that the methods employed in northern Europe might well repay study by a travelling mission.

There is no doubt that the activities of the County War Agricultural Committees will have a great influence on the dissemination of technical information to farmers in Great Britain. In many cases their problem is to grade up the weaker farmers towards the level of the better ones : not so much of developing new knowledge but rather of bringing into general acceptance the methods that have been practised on progressive farms for years. In duties of this kind the committees must have obtained a clearer and much more detailed picture of the state of English farms and the technical needs of English farmers than ever before. In the discussion, certain speakers advocated the retention of the agricultural committees in some modified form after the War. However this may be, the large body of workers now engaged on advisory work on behalf of the committees are building up a body of knowledge and experience that should be invaluable when, as we hope, science will have to serve practice in a planned post-war agriculture.

RECENT PROGRESS IN HEAT TRANSFER*

By PROF. C. H. LANDER, C.B.E.

Linking theory with practice is always beset with difficulties, and in no branch of engineering science are these greater than in heat transfer. In a modern boiler, for example, heat is conveyed from the fuel to the water-tubes by direct radiation from the firebed, and from incandescent soot particles, carbon dioxide and water vapour in the furnace gases, as well as by reflected radiation from surrounding refractories, and by convection from the gases. The rational approach to such a complex set of conditions is undoubtedly first to determine the fundamental laws of radiation, convection, etc., and then to apply them in building up a picture of what is happening in the actual furnace. Ways of improvement can then be foretold, and new designs worked out.

The fundamental laws of heat transfer are now fairly well known, but appliances involving heat transfer are still designed largely by trial and error, and any departure from traditional design is still viewed by many with apprehension. While it is no doubt true that the quickest way to design an appliance that will work is usually to follow well-tried principles, it is only by persevering with attempts to rationalize our knowledge that the best use can be made of science, and the engineer given the fullest help in his struggle towards increased efficiency.

---

* Substance of the opening paper at a discussion at the Institution of Mechanical Engineers on April 24.

Since radiation and convection are distinct phenomena, obeying different laws, they must be treated independently; and it is convenient also to consider separately heat transfer to evaporating liquids, and from condensing vapours, although they both bear a relation to convection.

Radiation and Emissivity

In heat transfer problems, the engineer is concerned only with the radiant energy emitted by all matter with increasing intensity as its temperature rises, commonly known as 'heat radiation'. The laws of black-body radiation are well known, but numerical calculations entail a knowledge of emissivity, which, since most actual surfaces are selective emitters, changes with temperature. Nothing like a full range of values has yet been determined, and the exact condition of industrial surfaces often cannot be specified.

There is still much to be learned about the selective emission of hot gases and flames. Water vapour and carbon dioxide, being products of combustion of all ordinary fuels, are of particular interest. Schack, in 1924, attempted calculations from infra-red absorption data, but there was so much uncertainty about the limits of the absorption bands, and the variation of the coefficient of absorption within them, that probably the most important outcome of his work was that it led others to make direct measurements. Their results agreed well for carbon dioxide, but were at variance for water vapour. Emissivity was given for different values of the product of the partial pressure and the thickness of the gas layer, and so tacitly assumed that the radiation depends only upon the total number of radiating molecules, and not upon whether they are spread out over a thicker layer with a smaller partial pressure, or compressed into a thinner layer with a higher partial pressure. Eckert and McCaig independently, however, have shown that for water vapour, although not for carbon dioxide, the emission may depend to a considerable degree upon the partial pressure and thickness of the gas layer separately, as well as upon their product.

In industrial plant, with flue gases, or gases containing steam, gas radiation may far outweigh convection. Thus Fishenden, measuring directly the heat transfer from the products of combustion of town's gas, flowing at 2–3 ft. a second through a 1-ft. pipe, found gas radiation varying from three times convection at 1,000° F. to ten times at 2,000° F. Admittedly, the velocities were low, but at higher temperatures, such as are found in many industrial furnaces, the relative importance of gas radiation rapidly increases.

So far, no really systematic experiments have been made on the emission from luminous gases or flames. If the suspended particles causing the luminosity are opaque, the emission, like that for non-luminous radiation, increases according to an exponential law, but for particles small enough to be partially transparent the case is much more complicated. There have been various attempts to evaluate furnace radiation, or to devise instruments for measuring it, but only on arbitrary and empirical lines.

Convection

The recent development of dimensional methods of correlating convection data has widened their range of application, and so greatly accelerated progress. Thus, experiments under pressure with surfaces only a few inches high may be used to deduce the heat transfer from surfaces several feet high at atmospheric pressure; or experiments in gases may be used to deduce the heat transfer in liquids. The most important dimensionless groups used in heat transfer are as follows:

The *Reynolds number* or *Re*, Vl/ν, or (velocity × characteristic linear dimension)/(kinematic viscosity), which determines the distribution of velocity in a stream of fluid flowing past a surface.

The *Prandtl number* or *Pr*, $c\nu/k$, or (specific heat per unit volume at constant pressure × kinematic viscosity)/(thermal conductivity), which determines the distribution of temperature in a fluid, the distribution of velocity already being given by *Re*. For example, in flow through a pipe, the velocity distribution is determined by *Re*, the temperature distribution by both *Re* and *Pr*.

The *Grashof number*, or *Gr*, $ag\theta l^3/\nu^2$, or (coefficient of expansion × gravitational constant × temperature difference × cube of characteristic linear dimension)/(square of kinematic viscosity), which is used only in natural convection, where, together with *Pr*, it determines the distribution of both velocity and temperature.

The *Nusselt number*, or *Nu*, $Hl/k\theta$, or (heat transfer per unit area per unit time × linear dimension)/(thermal conductivity × temperature difference).

Natural convection. Saunders has shown that theory suggests a satisfactory correlation of natural convection data by relating *Nu* with *Gr.Pr*, since, although there is actually a slight residual effect of *Pr*, this is negligible except in the extreme case of mercury, for which *Pr* is exceptionally low. Experiment amply confirms this, and curves are now available over a wide range for vertical and horizontal planes, and vertical and horizontal cylinders.

The transfer of heat across a layer of fluid between a hot and a cold surface is an interesting case of natural convection. By plotting the ratio of actual heat transfer to calculated conduction the results for gases and liquids can be correlated. The results for parallel vertical surfaces, and for concentric horizontal or vertical cylinders, lie on the same curve, provided the ratio of outer to inner cylinder diameter is small, say less than about five.

Forced convection: Flow across banks of tubes. Data on heat transfer and pressure drop in the flow of gases across banks of tubes are vital in designing efficient economizer and superheater units, as well as many types of forced-circulation boilers and heat interchangers. The first systematic investigation was by Reiher in 1925. He measured the total heat transfer and pressure drop for two spacings of tubes, and for both 'in-line' and 'staggered' formations. His work, however, did not cover a wide enough range for deducing general laws, and it was not until Pierson, Huge and Grimison's work in 1937 that satisfactory correlation became feasible. It has now been shown that the heat transfer can be closely related to the velocity in the narrowest restriction between the tubes.

The designer will usually be concerned with obtaining the greatest possible heat transfer for a given pressure drop. For a given mass flow, the lower the velocity, the smaller the pressure drop, and the smaller also the heat transfer for any given surface. Hence a compromise is necessary between the limitations of pressure drop and of space.

Heat Transfer and Fluid Friction

Osborne Reynolds, in 1874, pointed out the analogy between the transfer of heat and the transfer of momentum through an eddying fluid. Recently, with the conception of a more or less stationary film of fluid in contact with the surface, it has been realized that Reynolds' theory must be modified to take account of the two successive stages of heat transfer, first through the stationary film by conduction, and then into the core of the fluid by turbulence.

Boiling Liquids

Three distinct stages are now recognized in the boiling of liquids. The first stage, in which there is no appreciable bubbling, corresponds to the heating-up process before the boiling point has been reached. In the second stage, chains of bubbles rise from the heating surface, their sweeping and stirring effect increasing with the violence of the boiling. As the temperature difference is increased, there comes the third stage, in which the vapour bubbles tend to merge, until they may ultimately form a continuous layer over the heating surface. In the first stage, the heat transfer can be calculated from the appropriate convection data. In the second, or bubbling, stage, the heat transfer is relatively very high, and increases with the temperature difference until the final, or 'film', stage is approached. A sharp decrease then occurs, owing to the blanketing effect of the vapour layer. Hence, there is an optimum temperature difference, which depends upon the nature and condition of the surface, and particularly upon whether or not it is wettable.

Experiments on boiling liquids are of exceptional difficulty for, if the load is high, there may be considerable temperature differences both through, and over the surface of, even metal heating surfaces. Moreover, surface conditions, which greatly influence the rate of heat transfer, may change with time. Thus it is not surprising that no altogether satisfactory correlation of the experimental data has yet been achieved, although many attempts have been made. Surface tension and viscosity, however, are known to be important factors.

Condensing Steam

Nowadays, in designing condensers and evaporators it is essential to know the heat transfer coefficients from condensing steam. The condition of the surface is a very important factor. On a rough surface, free from grease, the condensate spreads out in a continuous film; but on a smooth, greasy surface it tends to form in separate droplets, giving five or ten times the heat transfer of a film. Consequently, much interest is being shown in finding effective 'promoters' of dropwise condensation.

Small proportions of air in steam, by introducing an additional thermal resistance, greatly reduce the heat transfer.

Conclusions

During recent years the engineer has looked more and more to fundamental science for help in his problems of design and working, and, on the other hand, the pure scientist has shown an increasing readiness to admit the importance of industrial applications. Although in full-scale plant, even when scientifically controlled, the conditions can never be specified with the accuracy possible in small-scale laboratory apparatus, key calculations can often give the designer a valuable pointer in deciding what changes are most likely to lead to improved results. There are still many gaps to be bridged, both in basic knowledge and in methods of using it, but much real progress has been made.

OBITUARIES

Prof. W. J. Young

Prof. W. J. Young, whose death occurred recently in Australia, was best known for the work on the breakdown of carbohydrate by yeast which was carried out in conjunction with the late Sir Arthur Harden between the years 1904 and 1913.

The classical researches of Harden and Young on the fermentation of carbohydrate by yeast established the phosphorylation of carbohydrate as an essential stage in the conversion of sugar to alcohol and carbon dioxide, and finally Young successfully accomplished the isolation of a hexose diphosphate. A quantitative relation was demonstrated, the amount of carbon dioxide liberated being proportional to the amount of inorganic phosphate which disappeared from the solution. The process of phosphorylation thus established as essential for the breakdown of carbohydrate by yeast was later shown by Embden and his colleagues to be also a necessary stage in the transformation of carbohydrate to lactic acid carried out by the muscle cell of the animal organism, and by Robison to play an important part in the ossification of cartilage. Harden and Young had laid the foundations of carbohydrate biochemistry, when they showed that it is by the process of phosphorylation that the living organism changes the starch and sugar molecules into the simple substances which are their final products.

After nearly ten years of fruitful co-operation with Harden, Young accepted the post of biochemist to the Institute of Tropical Medicine at Townsville, Australia, and left the Lister Institute. Some years later he was appointed professor of biochemistry in the University of Melbourne. There he became greatly interested in the teaching of biochemistry and built up a very fine department, paying special attention to the needs of medical students. His published papers during this period were concerned chiefly with the natural products of Australia and with problems brought to him for investigation.

Young was a man of wide interests and nothing gave him more pleasure than a friendly argument with his colleagues on every variety of subject. He was keenly interested in politics; and whatever subject he followed he devoted himself to it with enthusiasm, whether it was carbohydrate chemistry or the game of golf.

He will be remembered with affection by his former colleagues at the Lister Institute. He leaves a widow and a daughter, Sylvia, now practising medicine.

I. Smedley-MacLean.

Dr. W. E. Thrift

Dr. William Edward Thrift, provost of Trinity College, Dublin, who died on April 23, was born in 1870, and educated at the High School and at Trinity College, Dublin, where he obtained every distinction in mathematics and experimental physics for which it was possible for him to compete. He crowned his career as a student by obtaining a fellowship in mathematics and experimental science at the early age of twenty-six, and five years later, on the death of FitzGerald, was appointed as his successor in the chair of experimental and natural philosophy. This involved much teaching and administrative work, which was increased by the wideness of his interests, and the many demands for the benefit of his co-operation and advice on the boards of various institutions for the advancement of education and other important and beneficent purposes. In 1902 he was elected to the Science Section of the Council of the Royal Dublin Society, of which he remained a member until his death. He also acted for many years as financial adviser to the Representative Body of the Church of Ireland.

Shortly after his appointment, Prof. Thrift assisted in the editing of the collected works of his great predecessor, George Francis FitzGerald. Then came the task of planning the new physical laboratory which was provided for Trinity College by the munificence of the late Earl of Iveagh, and in 1908 he played a prominent part in making the local arrangements needed for the visit of the British Association to Dublin. A few years later he edited the fourth edition of Preston's "Light", and added a number of sections, bringing that valuable work up to date.

The demands on Prof. Thrift's time, however, became more and more insistent, and his election as one of the representatives of the University of Dublin in Dail Eireann in 1922 (a seat which he retained until the abolition of university representation in 1937) effectively prevented his further participation in work of a purely scientific nature, apart from the lecturing and teaching duties of his chair. Prof. Thrift became a senior fellow of Trinity College in 1928, vice-provost in 1935, and provost in 1937, a position the onerous duties of which he worthily carried out, even when they were rendered doubly difficult by the failing health which marked his closing years.

Prof. Thrift was an excellent lecturer—especially to senior students—and a sympathetic, though critical, examiner. Although debarred by his many activities from undertaking much serious research work himself, he was always most anxious to encourage and assist in that of his students, and his quick grasp of a subject, combined with his keen critical judgment, were of great help to all who sought his aid in their various problems. He was the kindest and most considerate of men to those who had the good fortune to study or work under him, and has given them good cause to feel that they have lost a friend whose name they will long remember with affection and esteem.

H. H. Poole.

We regret to announce the following deaths:

Dr. Herbert Fox, professor of comparative pathology in the University of Philadelphia and director of the Laboratory of Comparative Pathology, Zoological Society of Philadelphia, and author of "Disease in Captive Animals and Birds", aged sixty-one.

Dr. Jacob Reighard, emeritus professor of zoology at the University of Michigan, on February 14, aged eighty.

Dr. C. D. Sherborn, associate of the Linnean Society, compiler of the "Index Animalium", on June 21.

Mr. E. J. Wortley, C.M.G., formerly director of agriculture, Trinidad, on April 27.

NEWS and VIEWS

The Right Hon. Lord Hankey, P.C., G.C.B., G.C.M.G., G.C.V.O.

The election of Lord Hankey as fellow of the Royal Society under Statute 12 recognizes in a most fitting way his unremitting work to secure the recognition of the part which science and scientific men can play in the successful prosecution of the War. When the Scientific Advisory Committee was set up in April 1940, with the status of a Sub-Committee of the War Cabinet, Lord Hankey was appointed its chairman. He brought to it his unrivalled knowledge not only of the machinery of government but also of the diverse ways in which science was already being called upon by the Service and Supply Departments. But to knowledge there was added a warm personal sympathy with the desire of scientific men to give still more. Unfortunately, the time has not yet come to tell the whole story of the work of the Scientific Advisory Committee or of the Engineering Advisory Committee which was appointed later, also under Lord Hankey's chairmanship, to watch over the fuller utilization of engineering knowledge and ability. Sufficient is known, however, to make it clear that these Committees have more than justified their appointment. Lord Hankey vacated the chairmanship of the Scientific Advisory Committee and of the Engineering Advisory Committee when he left the Government earlier this year, but he has retained his charge of the Technical Personnel Committee, which continues vigorously to ensure that a sufficient supply of scientifically trained men is available for the continuing demands of the Services and war industries.

New Foreign Members of the Royal Society

The following have been elected foreign members of the Royal Society: Prof. Alfred N. Richards, professor of pharmacology in the University of Pennsylvania; Prof. L. Ruzicka, professor of organic chemistry in the Federal Technical College, Zurich; Prof. N. I. Vavilov, of Leningrad and Moscow; Prof. I. M. Vinogradov, of Moscow.

Prof. Alfred N. Richards

Prof. Alfred Newton Richards, who is now the vice-president of the University of Pennsylvania, with special responsibility for its important Medical School, has been engaged for a large part of his working life in experimental researches on the method of formation of urine by the kidney, over a wide range of vertebrate types. By original methods of great beauty and refinement, he has provided some of the most important available evidence concerning this excretory function. During the War of 1914–18, he crossed the Atlantic at short notice, in 1917, to collaborate with Dr. (now Sir Henry) Dale and the late Dr. P. P. Laidlaw in researches on traumatic shock, and joined with these workers in publications on the action of histamine and on related problems. Last year Prof. Richards became the first chairman of the newly appointed Committee on Medical Research of the United States, under the Office of Scientific Research and Development. No man is more fitted than he to promote the friendly collaboration in medical researches of the whole English-speaking world, both now and after the War.

Prof. L. Ruzicka

THE arrival, all too infrequently, of neatly blue-bound reprints continues to remind us of the energetic prosecution of the steroid hormone field by the school of chemistry in Zurich. Two and a half years ago we had the pleasure of referring to Prof. L. Ruzicka's election as a Nobel Laureate for the year 1939—an honour which he shared with Prof. Butenandt (NATURE, 144, 858; 1939). A brief account was given there of the work for which the award was made. To-day we welcome Prof. Ruzicka's election to the foreign membership of the Royal Society. His work forms the basis of the advances leading to the whole subject of the steroid hormones. It will be remembered that his great contribution consisted in his recognition of the importance of the residual part of the sterol molecule which remained after removal of the side chain. With characteristic insight Ruzicka realized that which the Göttingen workers had failed to see; namely, that the cyclopentenophenanthrene nucleus left after the above operations presented a jumping-off ground for further important investigations. There followed that brilliant series of researches leading to the male hormone progesterone, corticosterone and so on. It will be recalled that his early publications resulted in one of the most bitter polemics in science the century has known. Since the Nobel award, Ruzicka's main work has been the extension and amplification of the various substances that can be made from sterol disintegration. Numerous papers have appeared from his laboratory, many of which have recently arrived in Great Britain.

Prof. N. I. Vavilov

PROF. NICHOLAS IVANOVITCH VAVILOV's most important work has been on the origin of cultivated plants. His method was to make well-planned expeditions to those regions where cultivated plants grow wild, and he obtained strong evidence that countries where a large number of varieties of a particular plant occurs are the actual areas of origin. Conditions favouring genetical instability would, he argued, probably lead to the formation of a new species. It is remarkable how narrow is the belt along which cultivated plants arose. Mexico and Central America are the source for the New World, and Abyssinia, Persia, Afghanistan and an extension of this zone across Northern India into China, furnished the Old World with its crops. Prof. Vavilov has discussed the close relations between the origins of cultivated plants, of animals, and of ancient civilizations. He is, however, no mere collector. His material was taken back to Russia and there grown and studied in detail. He has become the leading taxonomist of cultivated plants, and he has also done valuable plant-breeding work and made important contributions to genetical science. He is well known to British and American scientific workers, having studied at the John Innes Horticultural Institution and visited various research centres, such as Rothamsted and others in Great Britain and also in the United States; and his complete command of the English language and lively humour and social gifts have always made him a welcome guest. His election to this new distinction will cause much satisfaction to many in Great Britain.

Prof. I. M. Vinogradov

PROF. I. M. VINOGRADOV is a member of the Academy of Sciences of the U.S.S.R. and he is universally acknowledged as the world's foremost investigator in the analytic theory of numbers. For years past he has produced a succession of discoveries, some of which can be described in no other way than as epoch-making. Many others are of vital importance and have also made mathematical history. They are already part of the fundamental equipment which must be acquired by anyone who studies number-theory. Many problems, in which there seemed little or no hope of any progress, yielded to his methods, which combine a wonderful imagination, great power and comparative simplicity; their possibilities have not begun to be exhausted. His most famous work is associated with Goldbach's theorem that every even number is the sum of two prime numbers. This theorem has been known for about two hundred years, but has never been proved. Vinogradov proved that every sufficiently large odd number is the sum of three primes. This is a result of a type, so difficult to prove, that it was considered a notable achievement when progress was made about twenty years ago by Hardy and Littlewood; even though their proof depended upon making assumptions of a type as difficult to prove as the famous Riemann hypothesis. The importance of Vinogradov's results may be gauged from the pecuniary recognition given to him by the Soviet Government. Well known also is his new solution of Waring's problem, leading to results far more precise than those first discovered by Hardy and Littlewood.

Two Eminent German Men of Science

IN the first week of July occur the bicentenary of the birth of the German physicist and writer, Georg Christoph Lichtenberg, of Göttingen, and the centenary of the birth of the German chemist, Albert Ladenburg, both of whom were well known in British scientific circles. Lichtenberg was born on July 1, 1742, at Oberramstadt near Darmstadt, and was the youngest child in a family of eighteen. As a youth he became a hunchback and was thus confined more or less to sedentary occupations. Entering the University of Göttingen at the age of twenty-one, he afterwards worked at the Observatory and when twenty-eight was made professor of mathematics. His first visit to England was made in 1770; his second in 1774. He was then made a fellow of the Royal Society. Returning to Göttingen in 1775, he became tutor to the Dukes of Clarence, Cumberland and Cambridge, and two years later was chosen to succeed Erxleben in the chair of physics, a post he held until his death on February 24, 1799. As a physicist he is remembered for his observations on the figures produced by fine dust on the surfaces of electrified plane surfaces. His electrical experiments led to a correspondence with Volta. Lichtenberg was also well known as a friend of Garrick and a writer on Hogarth.

Albert Ladenberg was born on July 2, 1842, at Mannheim, his parents being Jews. From Karlsruhe Polytechnic he went to Heidelberg to work under Bunsen and Kirchhoff, and he afterwards worked with Kekulé at Ghent and with Wurtz and Friedel in Paris. In 1872 he was appointed professor of chemistry at Kiel, and it was there that he began his important researches on vegetable alkaloids. In 1889 he became professor of chemistry in the University of Breslau and he held this position until 1909. He died on August 15, 1911. While yet a *privatdocent*, Ladenburg began to lecture on the history of chemistry, and during the space of forty years various editions of his "History of the Development of Chemistry during the past 100 Years" appeared in German, French and English. In Great Britain he was awarded the Davy Medal of the Royal Society and the Hanbury Medal, and was made an honorary member of the Chemical Society. A memorial lecture on his life and work was delivered to the Chemical Society by Dr. Kipping on October 23, 1913.

Mineral Resources and the Atlantic Charter

THE Conference on "Mineral Resources and the Atlantic Charter", arranged by the Division for the Social and International Relations of Science of the British Association, is to be held in the theatre of the London School of Hygiene and Tropical Medicine, Keppel Street, Bloomsbury, London, on July 24 and 25. There will be morning and afternoon sessions on each day, beginning at 10 a.m. and 2.15 p.m. The subjects of the successive sessions are intended, broadly speaking, to be classified respectively as: (1) distributional, in the geological and geographical aspects; (2) the preceding considerations as applicable to certain mineral products; (3) new sources and materials; (4) economic and planning considerations. The Conference will be opened by Sir Richard Gregory, president of the Association, and the chair at the successive sessions will be taken by Sir Thomas Holland, Sir William Larke, Dr. C. H. Desch and the Right Hon. Sir Stafford Cripps. Among expected speakers are Prof. H. H. Read, Prof. C. B. Fawcett, Prof. W. R. Jones, Sir Lewis Fermor, Dr. E. F. Armstrong, Dr. W. H. Hatfield, Dr. L. Dudley Stamp and Prof. J. G. Smith. Admission to the Conference will be by ticket, obtainable from the British Association, Burlington House, London, W.1; tickets will be issued, so far as accommodation in the theatre permits, on or after July 13.

Psychology of Hate

DR. ERICH FROMM, in a recent report to the *Journal of the American Home Economics Association*, discussed the two kinds of hatred which he claims exist. One is what he calls the "counterpoint of life". It is rational hatred, aroused by an attack on life, freedom, country, some person or institution we love. Such hatred is necessary for winning a war against aggression. "People must love what they are defending, in order to hate their attackers effectively." The other kind of hatred, which he calls "character-conditioned", was made use of by the Nazis in recruiting their party. The bulk of their recruits came from the lower middle class, who had led a starved and frustrated life socially and economically, particularly since 1918, in Germany. This led to tremendous irrational hatred and destructiveness which could only be expressed in small doses before the Nazi party offered an outlet.

"Destructiveness", says Dr. Fromm, "is the result of unlived life." He believes that this kind of irrational or character-conditioned hatred, which is all too common in our culture, results from the blocking of spontaneity and self-expression in childhood. Parents and teachers have many ways of discouraging self-development in children, from open intimidation to the subtle, 'sweet' type of authority which does not forbid, but says "I know you won't want to do that". Such children grow up with so little confidence in their own wishes and emotions that they can neither love nor hate constructively. Always dependent on other people even for their opinions, they are ready to follow a leader blindly. Their apparent submissiveness hides a dangerous amount of sadistic aggression, ready to be unleashed at the command of a *Führer*. But Dr. Fromm believes that this irrational hatred, utilized by the Germans, Italians and Japanese, is much less effective for winning wars than the positive kind of savagery shown by the Chinese and the Russians in defending their homes. The latter kind of hatred arises only when people are fighting for something they love. While Nazism pretends to fight for the life and existence of the German people, it is basically a movement of nihilism profoundly attracted by destruction. Its motto was adequately expressed by a speech once made by a Fascist officer who ended: "Long live death".

Broadcasts on American Thought and Culture

A NEW series of short-wave broadcasts under the auspices of the American Philosophical Society was inaugurated on April 24 over the non-commercial short-wave radio station WRUL. The world-wide significance of American thought and achievement in the present crisis in our civilization will form the general background of the series; distinguished American authorities will deliver a series of addresses, each in his special field—scientific, sociological and cultural. The American Philosophical Society and the World Wide Broadcasting Foundation have arranged to send out this series of short-wave broadcasts over WRUL from the Society's Hall in historic Independence Square, Philadelphia. They will be directed primarily to countries overseas where the English language is spoken and understood, and where there is still interest in the progress of science and learning and faith in a democratic form of government. WRUL is planning to translate a number of these outstanding talks into other languages for many of the countries covered by its beams; the station now broadcasts in twenty-two languages.

The John Innes Horticultural Institution

THE report of the thirty-second year of the John Innes Horticultural Institute covers the activities during 1942. A considerable number of changes of staff, including the resignations of such well-known individuals as C. Pellew, D. de Winton and B. Schafer, have taken place. Many of the staff have left to take up Government work. In addition, a serious drop in income as a result of war damage to property owned by the Trust has necessitated some reorganization. Nevertheless, an imposing series of research papers (more than fifty) on a large range of subjects, together with several important discoveries, indicate that the Institution is as vigorous as ever.

Among the new results may be mentioned the discovery of a method for testing incompatibility of pollen *in vitro*, the production of polyploid apples and pears by heat treatment, the successful hybridization of *Phaseolus vulgaris* and *P. multiflorus*, and the discovery of the plant with probably the highest chromosome number among wild Angiosperms—*Morus nigra* ($2n = 308$). Highly important work is developing from the theory of polygenes and from the discovery that inert parts of the chromosome may be identified by starvation of nucleic acid. The publication of the John Innes leaflets on horticultural subjects has met with a popular demand, and there has been a large increase in advisory work on horticulture. This is a new and welcome branch of the activities of the John Innes.

A New X-Ray Synthesis

S. H. Yü has recently developed a synthesis of X-ray intensity data which, it is claimed, has certain advantages over the Patterson synthesis. An account of the method has been published in NATURE (June 6, 1942, p.638). S. H. Yü and C. P. Ho have illustrated the synthesis by a detailed treatment of iron pyrites (*Science Records, Academica Sinica*, 1; 1942). In a further study, submitted to NATURE, they have investigated the effect of the approximations necessary in practice, and the conditions for obtaining satisfactory results from the new method. It is necessary to use a mean value for the variation of atomic structure factor with angle; that given by the Thomas-Fermi atom proves to be a sufficient approximation. For a good determination of the atomic parameters the edge of the unit cell must be divided into at least 100 parts. For the synthesis described in NATURE it is necessary to know at least 13 orders of $h00$ to get a good result, but it is shown that it is possible to modify the method so that it is applicable to a smaller number. Yü and Ho are to be congratulated on maintaining scientific research in China in difficult circumstances, and the application of the method to unknown structures will be awaited with interest.

Shortage of Drugs in France

ACCORDING to the *Journal of the American Medical Association* of March 25, the Academy of Medicine of Paris has for months been studying the problem of the shortage of indispensable drugs. At the suggestion of Dr. Georges Duhamel, a committee has been formed to publish periodically a list of drugs and chemical products becoming rare. The majority of raw materials come from foreign countries, and importation of these has mostly been cut off. A second reason consists in the difficulty of transport and the dearth of packing material. In the latest list presented to the Academy the following were said to be extremely scarce or entirely absent: caffeine, theobromine, iodine, camphor, boric acid and its derivatives, quinine, opium and its alkaloids, glycerine, cod liver oil, starch, dextrose, mustard meal, lactose, tartaric and citric acids, insulin, and many other chemical and vegetable products.

Lady Tata Memorial Trust

THE Trustees of the Lady Tata Memorial Fund announce that, on the recommendation of the Scientific Advisory Committee, they have agreed, if circumstances permit, to make the following awards for research in blood diseases, with special reference to leukæmia, in the academic year beginning on October 1, 1942. Grants for research expenses: Prof. J. Furth (New York); Dr. P. A. Gorer (London); Dr. A. H. T. Robb-Smith (Oxford); Prof. L. Doljanski (Jerusalem). Part-time personal grant for assistance: Dr. W. Jacobson (Cambridge).

The Night Sky in July

THE moon is new on July 13d. 12h. 03m. U.T. and full on July 27d. 19h. 14m. There are no occultations of any bright stars during the month. The following conjunctions occur: July 3d. 23h., Venus in conjunction with Saturn, Venus 0·1° N.; July 9d. 21h., Saturn in conjunction with the moon, Saturn 3° N.; July 10d. 11h., Venus in conjunction with the moon, Venus 4° N.; July 11d. 15h., Mercury in conjunction with the moon, Mercury 3° N.; July 12d. 10h., Jupiter in conjunction with the moon, Jupiter 4° N.; July 16d. 00h., Mars in conjunction with the moon, Mars 3° N.; July 18d. 08h., Mercury in conjunction with Jupiter, Mercury 0·4° S.; July 30, 10h., Mars in conjunction with Regulus, Mars 0·7° N. Mercury is a morning star and is in greatest elongation on July 6 when it is 21° W. Venus is a morning star and souths at 9h. 50m. in the middle of the month. Mars is too close to the sun to be well observed. Jupiter is a morning star, in Gemini, and rises about 2h. 40m. in the middle of the month. Saturn is a morning star and souths about three hours before the sun in the middle of the month. Comet Grigg-Skjellerup can be observed with a small telescope; an ephemeris appeared in NATURE of June 6, p. 636. The earth is at aphelion on July 6.

Announcements

MR. A. GOUGE has been elected president of the Royal Aeronautical Society for the year 1942–43, and Mr. E. F. Relf, superintendent of the Aerodynamics Department, National Physical Laboratory, and Dr. H. Roxbee-Cox, deputy director of scientific research at the Ministry of Aircraft Production, have been elected vice-presidents.

AT the seventy-ninth annual general meeting of the Institution of Gas Engineers, held on June 10, Mr. E. V. Evans, general manager of the South Metropolitan Gas Company, was elected president for the year 1942–43. Mr. Evans, who is also chairman of the Council of the Gas Research Board, is the first chemist to occupy the presidency of the Institution of Gas Engineers.

THE Association of Scientific Workers (with the collaboration of the Federation of Ayrshire Scientific Film Societies) has arranged a Conference on "The Scientific Film and Scientific Film Societies", to be held in two sections: in Ayr on August 1 and 2, and in London on August 16. The Conference will discuss the possibilities of scientific film societies run by branches of the Association of Scientific Workers to give science films the widest possible showing, and will direct public attention to these activities and to the need for increased and co-ordinated production of science films.

A New Type of Microphotometer

THE following note contains a short description of the principle of a new type of microphotometer, the details of which will be published elsewhere. The main feature of this new device is that it gives a practically instantaneous record of the blackening curve, that is, the distribution of transparency of a photographic plate or a similar object along a straight line, which appears on a fluorescent screen and therefore permits a quick visual survey of the blackening distribution in a whole plate. The new instrument is comparatively small, easily transportable from one place to another, and it contains no delicate or expensive mechanical parts. It can, if necessary, be put together in any laboratory workshop from parts of existing apparatus.

The instrument consists of two separate parts, the 'receiver' and the 'recorder', which are only electrically connected. The receiver consists of a light source (small incandescent lamp), a slit on which the light from the source is concentrated, a microscope objective which forms a reduced image of the slit on the plate under investigation, and a photo-electric cell (cæsium, gas-filled) on the cathode of which the light is finally concentrated. The plate is fixed to one prong of an electromagnetic tuning fork operated by 50 c./sec. A.C. so that it performs a simple harmonic oscillation in its own plane and normal to the direction of the beam.

The recorder consists mainly of a cathode ray oscillograph of commercial type with a two-stage linear amplifier for the deflecting potential in the vertical direction. The input voltage of this amplifier is taken across a high resistance in the anode circuit of the photocell. The deflexion of the cathode ray is therefore proportional to the transparency of the plate at the particular point just passing the slit image. The potential for the deflexion in the horizontal direction is supplied by the same A.C. which operates the tuning fork in such a way that the two oscillations, the mechanical one of the plate and the electrical one of the deflecting field, are exactly in phase. The horizontal deflexion of the cathode ray is therefore exactly proportional to the displacement of the plate. Thus the recorder plots automatically the blackening curve along a line on the plate equal in length to twice the amplitude of its vibration.

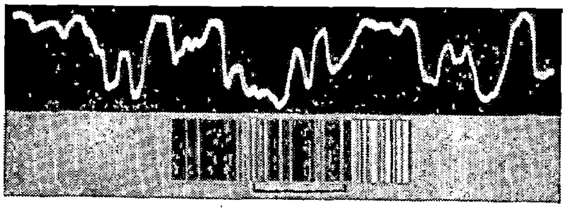

Fig. 1.

UPPER: BLACKENING CURVE OF A PART OF THE PHOTOGRAPH OF A BAND SPECTRUM.

LOWER: ENLARGED POSITIVE OF THE SAME BAND SPECTRUM, THE RECORDED REGION BEING MARKED BELOW.

The magnification of the instrument, that is, the ratio of the horizontal distance of two corresponding points on the screen and on the plate, can be easily and quickly changed by changing the amplitude of the vibration of the fork between about 25 and 500. It is obviously also easy to change the scale of the recording curve in the vertical direction. Hence the instrument can be adjusted to any particular object within a few minutes.

The whole vibrating mechanism can be shifted in the direction of the vibration by means of a micrometer screw. By this procedure the picture on the screen is bodily shifted in a horizontal direction so that different parts of the blackening curve come successively into the field of observation. In this way the blackening curve can be obtained over the whole length of the plate and, if necessary, along a whole set of parallel lines.

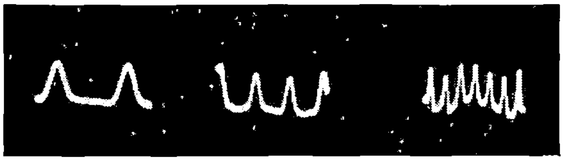

Fig. 2.

RECORDS OF THE BLACKENING CURVE ALONG A MICROSCOPIC SCALE, CONSISTING OF PARALLEL LINES 0·1 MM. APART, TAKEN WITH DIFFERENT MAGNIFICATIONS.

The different parts of the curve can, if so desired, be traced or photographed and afterwards put together for recording purposes. Fig. 1 is an example of such a record. The upper part represents the blackening curve along a certain part of a band spectrum shown in the lower part of the figure. The original magnification factor in this case is approximately 60. Fig. 2 shows the blackening curve along a microscopic scale consisting of parallel lines 0·1 mm. apart, taken with different amplitudes of fork vibration. The magnification factors were 380, 180 and 80 respectively. Although these curves perhaps show less detail than those obtained with the usual kind of microphotometer (mostly because of their thickness) this disadvantage will for many purposes be more than balanced by the advantages mentioned in this note.

Valency and Orientation

MANY rules have been given[1] with the object of summarizing in an approximate manner the directive effect of substituents on further substitution in benzene. The values of these rules are practical, theoretical and didactic. The instructive value of many of them is often slight because of their complexity, and it is primarily in an attempt to overcome this complexity that I wish to suggest yet another. It is based upon a simple valency rule I have proposed for use in the teaching of elementary chemistry[2]. Like this valency rule, the new orientation rule is in accord with the simple electronic theory of valency; in particular, it is an alternative expression of the simplicities of the somewhat complicated electronic orientation theories of C. K. Ingold[3] and R. Robinson[4]. It can be stated as follows:

If X be the atom attached to the benzene nucleus in a compound C_6H_5Y, then the group Y which contains X is an *ortho/para*-directing group when the valency of X is equal to or less than 4, and a *meta*-

directing group when the valency of *X* is greater than or equal to 4. The accompanying table contains examples illustrating the rule.

Directivity	Valency of atom (*X*) attached to benzene ring (2)	Examples of groups[1] (*Y*)
Predominantly *ortho/para*	0	$-\bar{\mathrm{O}}$ (phenoxide ion)
	1	$-\mathrm{Cl}$, $-\mathrm{Br}$, $-\mathrm{I}$.
	2	$-\mathrm{OH}$, $-\mathrm{O\ Me}$
	3	$-\mathrm{NH_2}$, $\mathrm{NMe_2}$, $-\mathrm{NHAc}$
	4	$-\mathrm{CH_3}$, $-\mathrm{CH_2COOH}$, $-\mathrm{CH_2CN}$
Predominantly *meta*	4	$-\mathrm{CHO}$, $-\mathrm{CN}$, $-\mathrm{COOH}$
	5	$-\mathrm{NO_2}$, $-\overset{+}{\mathrm{A}}\mathrm{sMe_3}$, $-\overset{+}{\mathrm{S}}\mathrm{bMe_3}$
	6	$-\mathrm{SO_2OH}$

There is gradual transition from *ortho/para* to *meta* directivity at X^{IV} but there is practically no ambiguity at any other valency for *X*. The iodonium group containing X^{III} is an exception, and such an exception, together with the duality of directive property which exists at X^{IV}, are to be attributed, as in many existing orientation rules, to the effect either of a formal positive charge on *X*, or of the tendency for such a positive charge to be on *X* due to the influence of adjacent atoms in *Y*. Accordingly, most of the X^{IV}-containing groups which are *meta*-directing either carry a formal positive charge on *X* (for example, sulphonium group), or carry an accumulation of 'negative' atoms or groups (for example, $-\mathrm{CCl_3}$, $-\mathrm{C(COOEt)_3}$), or are unsaturated and liable to polarization (for example, $-\underset{|}{\mathrm{C}}{=}\mathrm{O} \rightarrow -\overset{+}{\underset{|}{\mathrm{C}}}-\overset{-}{\mathrm{O}}$). This tendency to polarization is not so great when *X* is attached to another *X* by a double or triple bond (for example, $-\mathrm{C_6H_5}$, $-\mathrm{CH{:}CH.COO}R$, and $-\mathrm{C{\vdots}C.COO}R$ are predominantly *ortho/para*-directing). Even with these modifications, none of which are new, the transition from *ortho/para* to *meta* directivity at X^{IV} remains the striking feature of the new rule.

Calcium Nutrition of the Fœtus

Andersch and Oberst[1] have reported the total and ultrafiltrable calcium and the total protein of sera of twenty-five parturient women and their new-born. The median values for mothers and offspring, respectively, were: total Ca 10·3, 11·7 mgm. per 100 ml.; ultrafiltrable Ca 5·4, 5·3 mgm. per 100 ml.; total proteins 6·46, 5·43 per cent.

The McLean-Hastings mass law equation

$$\frac{[\mathrm{Ca}^{++}]\,[\mathrm{Protein}^{=}]}{[\mathrm{Ca\ Proteinate}]} = K_{\mathrm{Ca\ Proteinate}},$$

can be used with data of the above type[2] and, although the partition of serum calcium between ultrafiltrable and colloidal forms is not an equilibrium governed solely by calcium and protein concentrations[2,3], the equation yields consistent results when applied to means of large groups of data.

The above data yield *p*K values of 2·11 for mothers and 2·37 for offspring. Since the maternal and fœtal ultrafiltrable calcium levels are in equilibrium, this increased calcium-binding power of fœtal plasma colloids allows greater quantities of calcium to be transferred to the fœtal circulation, held in solution and transported, than would be the case if maternal and fœtal colloids were identical. If the Andersch-Oberst data are recalculated with the assumption that there is no difference between the maternal and fœtal colloids, then it is found that the total serum calcium level would have been 9·5 mgm. Thus the increased carrying capacity is 2·2 mgm. Ca per 100 ml. plasma; or, making the same assumption, the data can be recalculated to show that in order to maintain the total serum calcium level at 11·7 mgm., with an ultrafiltrable calcium level of 5·3 mgm., the fœtal proteins would have to be increased to 8·24 per cent.

The necessity of such a mechanism is clear since the fœtus is in competition with the mother and, in spite of having a much smaller blood volume for transport purposes, must deposit in the skeleton almost as much calcium as the mother stores to meet future lactation requirements.

This special type (or distribution) of plasma colloids confers an advantage on the fœtus in calcium transport similar to that of the special fœtal type of hæmoglobin in oxygen transport.

The Polygene Concept

Drs. Gordon and Sang[1] have, very properly directed attention to the value of studies on the interrelations of environment and genic expression Some of the most fascinating problems of genetics are to be found in this field; indeed, we need go no further than the investigations which these two authors have made on the manifestation of the gen 'Antennaless' in *Drosophila melanogaster*[2] to see how much can be accomplished by such researches.

Now, as Gordon and Sang point out, this question also constitutes one of the major problems in the study of polygenic inheritance; but, in so far as ou aim is to investigate the heritable portion of polygenic variation, the problem raised by non-heritabl influences is a technical one. Non-heritable effect constitute a source of what Fisher has called "error" variation and, as such, affect the precision, though not, in an adequately planned experiment, the rigou of the results[3]. Investigations of the kind made and advocated by Gordon and Sang can be valuable in showing us how to control this error and increas precision; but, whether such control is exercised o not, experiments which are planned, conducted and analysed so as to yield a valid estimate of error wi permit sound conclusions to be drawn. It is equally true that no matter how good control over th sources of error may be, the full value of the observations cannot be extracted unless this error is estimated in the way which is possible only with sound experimental design. The statistical techniques necessar for the conduct of such experiments are more familiar to agronomists than to geneticists, who have had little occasion to use them in the past. Polygenic investigations will, however, require that genetical experimenters become as familiar as agronomists with the principles of experimental design; more especially because these same principles must be used to develop methods as appropriate to the solution of genetical problems as the randomized block, latin square, etc., are to field trials. It would be rash, perhaps, to suppose that all the difficulties of polygenic investigation can be overcome by these means, but suitable experimental design is clearly the primary requirement.

I venture to think that my own experiments[4,5] have been adequate from this point of view, and that, therefore, a certain degree of confidence may be placed in my results. (It should be stated that, for reasons of space, only the outlines of my analyses could be published in some instances.) In any event my experimental technique was sufficient to render it improbable that the results could, as Gordon and Sang suggest, be attributed to the sterility of females in the selection lines, for the following reason. I selected both for increased and decreased number of abdominal chætæ, and obtained a marked response in each direction. Sterility also set in in both lines, with a consequent reduction in the larval population of each culture. It is difficult to see how this reduction could explain the selection results, for in one line it must then be supposed to have resulted in an increase in chæta number, while in the other it resulted in a decrease. Furthermore, a repetition of this selection experiment gave comparable results, even though larval crowding was artificially increased by doubling the number of parent flies per culture.

It may be remarked that, in my experience, reduced fertility appears to be an almost inevitable accompaniment of selective response in any polygenic character of *Drosophila melanogaster*. The reason is probably a mechanical one. Fertility itself must be polygenic and hence its controlling genes will be intermingled, along the chromosomes, with those other polygenes which control the character upon which selection is being practised. Now selective response, on my view, depends mainly on the action of recombination in breaking up polygenic combinations and so releasing heritable variability. Such recombination will affect the polygenic combinations controlling fertility equally with those controlling the character upon which selection is being directly exercised. Correlated response may then be expected to occur, and fertility will be reduced as the chæta number changes. Correlated response to selection would appear to be an inevitable property of polygenic inheritance, and it is of great help to us in understanding some features of evolutionary change, notably the degeneration of unused organs.

Furthermore, correlated response renders it nearly, if not quite, impossible to maintain the fertility of selected females, as Gordon and Sang propose. It also serves to emphasize the absolute necessity of adequate experimental design. K. MATHER.

Gordon and Sang[1], in commenting upon the important work of Mather[2] on polygenic inheritance, remark that the study of this will only become effective when certain experimental conditions are understood and allowed for. Might I add that there may be a further condition to be fulfilled for its satisfactory development?

It seems to me that it will be necessary first to face and to solve a real methodological difficulty inherent in any work involving the concept of polygenes. Many cases are familiar where several genes, independently known, interact to give certain effects. The evidence for the existence of these genes depends upon ordinary considerations such as the increase in variation seen in the F_2, and in the possibility of establishing so-called 'pure lines' of differing qualities out of the original stock.

In order to account for the behaviour in heredity of a variable quality the behaviour of which cannot be accounted for on the assumption that it depends upon the distribution of the members of a single gene-pair, it seems now to be assumed that its behaviour depends upon the distribution of the members of several such pairs, of which there may be no independent knowledge. If the number of such pairs invoked as relevant be increased just until they are sufficient to explain the observations, a weakness seems to appear in the procedure. The explanation offered becomes, it seems to me, simply epicyclic; that is, closely similar to the explanation of planetary motion by the postulate of any requisite number of epicycles. It will, as epicyclic explanations always will, explain anything: any ratio of types, any degree of the expression of a quality. But what is the scientific value of such an explanation?

Surely it will be necessary to base the estimate of the number of genes to be invoked as relevant on something other than an estimate of how wrong the assumption of a single gene-pair would make the results. Where is this other independent criterion to be sought, if the genes concerned have nearly negligible individual effects or even cannot be isolated?

Reflexion from Paper

THE optical effect described by Mr. Burke in NATURE of May 30, p. 613, is well known to the practical papermaker. In matching the tone of a 'white' paper it is essential to employ direct illumination and direct vision. Any angular deviation in lighting or vision gives rise to misleading tones of red or blue.

Dr. V. G. W. Harrison's ingenious explanation does not appear satisfactory for the following reasons: (1) The effect described is characteristic of plain uncoated papers, not 'art papers', which present a non-fibrous surface; (2) the angle at which the maximum effect is observed does not correspond with that of specular reflexion; (3) it explains a possible red colour but not a definite blue tone.

I suggest that the true explanation of this effect may be found in spectral diffraction of part of the reflected light. The orientation of the fibres in the cellulose and of the fibres in the paper produce a kind of grating from which the reflected light is partially diffracted into a spectrum, the red and blue ends of which at a particular distance cover the vision of the right and left eyes respectively.

A similar and more pronounced effect may be observed with certain specimens of polished chalcedony and opal in which it is certainly a diffraction effect, due to a finely striated structure of these minerals.

J. STRACHAN.

New Northfleet Paper Mills, Ltd.,
Kent.

MR. BURKE's observation regarding the reflexion from paper as viewed by the two eyes separately may have an explanation other than that suggested by Dr. Harrison (NATURE, May 30, p. 613). A simple comparator I have in use has magnesium carbonate block reflectors set substantially vertically and parallel to the plane of a large, tall window, so that these very excellent diffusing reflectors receive skylight at roughly 45° incidence. The light reflected normally is received on two first-surface mirrors arranged in a casing and viewed through a tube at one side, so that a square field divided by a barely perceptible vertical septum is observed. Customarily this instrument is set up so that the observer has the window at his left-hand side. Thus the left eye is somewhat exposed to direct light from the window, whereas the right eye is appreciably protected by shadow thrown by the nose. On changing from left to right eye a distinct difference is noticed in the blueness or redness of any near-white field examined, and this is greatly reduced by placing a screen so as to prevent much light from the window striking the left eye.

J. LEONARD BOWEN.

9 The Wiend,
Lower Bebington,
Wirral.

IN NATURE of May 30, Mr. E. Burke points out that "If an open book is illuminated fairly strongly from one side, for example, from over one shoulder, the general colour of the white paper is different for the two eyes when one or the other is closed". Dr. V. G. W. Harrison, commenting on this letter, regards this phenomenon as "due to selective specular reflexion from the paper".

I suggest, however, that this explanation is not the correct one. If one sits reading a book with the light coming over the left shoulder, the left eye is exposed to a certain amount of direct illumination by the light source, while the right eye is shielded from direct illumination by the nose and the nasal edge of its orbit, and is thus only illuminated by light reflected from the interior of the room. This is evident from the fact that while actually reading the book, one sees the illuminant by peripheral vision with the left eye, but not with the right. Under these conditions, the right eye is more dark-adapted than the left eye. Now from the Purkinje phenomenon we know that the subjective brightness of specific colours varies according to the degree of dark-adaptation of the eyes, and it is surely in this direction that the explanation of the phenomenon noticed by Mr. E. Burke is to be sought. Under the conditions described, the right eye would be employing 'rod vision' to a greater extent than the left eye, and differences of colour perception are to be expected.

It is, of course, true that the image of one and the same printed page occupies the foveal area of both retinas, but the phenomena of simultaneous colour contrast show us that central vision is not independent of the nature of the peripheral 'outfield'.

Dr. Harrison's explanation seems to be negatived by the fact that if book and reader are suddenly rotated through 180° without moving the illuminant, the phenomenon described persists unaltered for some time, until a new adaptation takes place.

Origins of Human Graphic Art

As a result of the publication of my note in NATURE of June 6, p. 637, Mr. J. Leonard Bowen, of Port Sunlight, Cheshire, sent me the enclosed letter which seemed to me of such interest that I have obtained his permission to publish it in NATURE. Mr. Bowen tells me that the monkeys were almost certainly the common rhesus monkey, *Macaca mulatta*.

JULIAN S. HUXLEY.

Zoological Society,
Regent's Park,
London, N.W.8.
June 11.

YOUR note on the "Origins of Human Graphic Art" reminds me of observations I made some years ago at Matheran, near Bombay. Large numbers of large long-tailed monkeys romp about this little hill station and afford much amusement to visitors. I frequently saw such monkeys trace the outline of one of their hands in the dust, using a twig held almost as one would hold a pencil. Other monkeys inspected the traced outlines with a show of interest, walking round and round the spot with what seemed to be an anxious manner.

J. LEONARD BOWEN.

Simplification of Musical Notation

(1) LIKE everything else which has grown up as a result of an evolutionary process, the present musical notation[1] has imperfections; yet it remains superior to our ordinary orthography. It is universally accepted, and there is nothing in it corresponding to the English 'ough' sounds, or to, for example, the differences in the French and Italian pronunciations of 'un' and 'le'.

(2) Apart from the coalescence of sharps and flats on keyboard instruments, the present notation fulfils Lord Brabazon's requirements without ambiguity or redundance.

(3) The present notation is not intended only for keyboard instruments. In music for string quartet

or unaccompanied choir, the distinction between sharps and flats can be made, and is made by good performers. The distinction is not simply of mathematical interest; it is easily perceptible to a moderately good ear. While equal temperament is a necessary evil in keyboard instruments and has no doubt come to stay, there is no point in enforcing it where it is unnecessary.

(4) The key signatures are introduced for convenience, not to make the music look difficult. For example, in the key of D major the notes F♯ and C♯ are constantly recurring, while F♮ and C♮ occur only exceptionally. The regularity is therefore noted once and for all at the beginning of the piece, and only the exceptions are noted afterwards. If key signatures were abolished and all accidentals inserted every time they occurred, the exceptions to the general regularity would tend to get overlooked in the mass of accidentals. This applies particularly to music written in such keys as B major.

(5) If equal temperament were to be adopted for all music, it would no doubt be possible to eliminate the signs for sharps and flats by writing on a staff of seven lines and six spaces to the octave, and taking the interval between a line and an adjacent space to represent a tempered semitone. Experience has shown, however, that such large staffs are not easy to read, even for an experienced performer. The original Great Stave of eleven lines had to be divided into two by the omission of the middle line for this very reason.

(6) The present system is admittedly awkward for the notation of certain modern music not based on the diatonic scales. However, such music is not likely to be studied by a beginner, and, indeed, still forms only a small part of the repertory.

The initial difficulties of the musical notation are no greater than those which face the student of a new language or a new branch of mathematics. No real progress will be made by trying to evade them.

Science and Science Teaching

Having listened to the discussions opened by Prof. Lancelot Hogben and by Mr. L. J. F. Brimble, reported in a recent issue of Nature[1], on the role of human applications in science teaching, it seems to me that something may be gained by examining, from a scientific point of view, the nature of science itself. Science, we are told, is a method of observation and classification of phenomena. But this is, metaphorically speaking, only its physiology. It has also an evolution and an ecology. How did it come into existence? In what surroundings does it flourish?

It is a sociological phenomenon, a function of human society, for every letter of it is the product of human minds working together, and of the fingers of more than one pair of hands. Moreover, it requires a certain state of social development before it can appear. During the greater part of the human era it has not existed; in some parts of the world it does not there to-day. The value of scientific method may seem as clear as noonday to us, but (taking samples of social life at random in space and time) this outlook has not been even the usual one.

Only in certain conditions has it been found 'paying' to use science, and therefore become customary to encourage it morally and financially. Only then has the germ of scientific method, always present in the human mind, made progress relative to other forms of mental activity. But in these circumstances science has 'paid' just because its findings proved true when put into *practice*. Its cultivation therefore depended on its verification, not 'in the test-tube' but 'in the works'. (This has extended recently to biology.) Here we have a two-way correlation between pure science and applied; neither can in fact exist without the other, like Newton's '"action" and "reaction"'.

Until recently it has been customary, both in authoritative appraisement and in teaching, to exalt pure science and neglect the interrelationship. Now, questioning these preconceptions, we must teach science as a form of human activity, as mankind's struggle to master Nature (including his own), wherein 'pure' and 'applied' are seen as parts of one whole, the strategy and tactics of man's war against ignorance and impotence. All science is applied knowledge, but some parts (the 'pure') have a wider field of applicability than others. What is not (ultimately) applicable is not science.

The test of the truth of an expressed scientific principle does not lie only in some original investigation in the past; it is still being tested in the present in its practical applications. Therefore there is no particular scientific merit in always teaching the original experimental method by which the principle was derived, or in a 'laboratory' method of experimental proof. How then, it will be asked, are we to awaken and keep alive in our students the investigatory spirit? Partly by description and reproduction of a few selected historic investigations as striking examples of scientific method. But these must be part only of a general treatment showing science in all its parts as a live, present-day inquisitive and progressive movement of mankind, illustrating its principles not only by historic derivations, but also largely by simple (for children) modern applications. Occasional serious discussion of projected or suggested applications will help to emphasize the importance of research. It seems worthy of consideration, too, whether we cannot cut out traditional treatment of some older principles, replacing them by wider generalizations in which they are included. Experimental technique should be taught only when it can be made to answer a question of genuine interest to the student.

In recent discussions on science teaching much has been said of the conflicting interests of future specialist and future 'general citizen', of future academic scientist and future technician, of 'humanist' and 'scientist'. But if the methods sketched above can be brought more into use, the whole of science teaching will be made more 'live', by being brought more into contact with the fronts on which mankind is advancing, to the benefit of all the categories of students mentioned, and so of mankind in general.

CHROMATIC BEHAVIOUR*

CHROMATIC behaviour of Vertebrata, Crustacea and Hirudinea depends on specialized pigmentary effector organs, which are diffusely branching cells in which pigment migrates to the centre or periphery, thereby offering more or less obstruction to incident radiation. Such cells are present in the integument (or scales) of nearly all cold-blooded vertebrates and of most Malacostraca. Light is the most universal stimulus to their reactions.

Photic responses of vertebrates and of Crustacea involve three components. Any one of them may predominate. Any one of them may be negligible. All of them may co-exist in one and the same species, contributing more or less to the ordinary rhythm of colour change. The three components are as follows:

(*a*) A *primary dermal* reaction, which is independent of the eyes. This is probably the most archaic, since it is the only type of photic response among Hirudinea which possess melanophores. It is also the more *characteristic* light reaction of such reptiles as Chameleo or Phrynosoma, possibly also of some elasmobranchs.

(*b*) A *secondary ocular* reaction (black background response) normally evoked by transferring an animal from darkness to superior illumination in light-absorbing surroundings. Light initiates this reaction when it falls on a *B*-area located in the ventral part of the retina of the vertebrate eye, the more dorsal ommatidia of the isopod and the dorso-central ommatidia of the crustacean eye.

(*c*) A *tertiary ocular* reaction (white background response) normally evoked by transferring animals from superior illumination in light-absorbing to superior illumination in light-scattering surroundings. Light initiates the reaction when it falls on a *W*-area dorsal to the *B*-area of the retina of the vertebrate eye, on the latero-ventral ommatidia of the isopod eye and on the ommatidia of the ventral periphery of the decapod eye.

The *primary* dermal response is partly autogenous, that is, it is evoked by direct action of light on the melanophores, and partly due to dermal photoreceptors which bring into play the same co-ordinating mechanism as (*b*) above. In all vertebrates, except possibly some teleosts, the *secondary* ocular response depends on *reflex* liberation of the *B*-substance of the pars intermedia of the pituitary gland. The *tertiary* ocular response is the latest component in the evolutionary series; and its control is different in different groups of vertebrates. To a greater or less extent in reptiles and in Teleostei, direct nervous control has *independently* established itself as a controlling process; but in Teleostei it seems to be superimposed on a more archaic type of indirect control through reflex liberation of some hormone. Study of colour changes of Amphibia, of the eel and of elasmobranchs points to the conclusion that some part of the pituitary gland is either the seat of the latter or controls the functional activity of another ductless gland which produces it, possibly the supra-renal.

Electrical and tactile stimulation of certain receptive areas of reptiles which have an acquired direct nervous control of the pigmentary effector system can evoke a reaction like the tertiary ocular response; but electrical and tactile stimulation rarely evokes generalized chromatic response of other vertebrates. We have insufficient information to justify general conclusions about the way in which temperature or moisture evokes response of land vertebrates or terrestrial Crustacea.

The fact that so many species of vertebrates which possess pigmentary effector organs display no striking colour change in response to normal changes of the environment is partly due: (*a*) to specific variation of the resting level of hormone concentrations in the blood; (*b*) to a delicate adjustment of ocular orientation and external illumination necessary for the production of separate secondary and tertiary light reactions; (*c*) to more or less insensitivity of the chromatophores to incident illumination.

Control of chromatic behaviour of Crustacea is due to reflex liberation of at least two hormones, of which one is produced by a gland in the neighbourhood of the eye itself. The sinus gland of the eye stalk of Decapoda produces a hormone the reflex liberation of which evokes the black background response of Brachyura and the white background response of decapods other than Brachyura.

MANUFACTURE OF OPTICAL GLASS IN CANADA

THE story of Research Enterprises Ltd., the body which has undertaken the production of optical glass and instruments in Canada, has been told by its president, Colonel W. E. Phillips, in a paper presented to the Engineering Institute of Canada in February last. It is a fascinating story of difficulties overcome by determination and ability.

It was in October 1939 that General MacNaughton suggested to the War Supply Department that consideration should be given to the production of optical parts in Canada, but at that time for various reasons the matter did not make any progress. Later, it was re-opened by the Department of Munitions and Supply in connexion with an urgent demand for binoculars. Further investigation showed that the requirements ranged from binoculars to dial sights, including such highly specialized instruments as range-finders. To meet this demand, Research Enterprises Ltd. was organized in August 1940 as a wholly Government-owned company, operating under the Ministry of Munitions with the full freedom of a private enterprise. The need for optical glass was the immediate justification for the creation of the company, but it was intended that this should be followed by the production of a variety of optical instruments. Conditions in Canada were, of course, quite different from those in Great Britain, where a long-established separate industry supplies optical glass blanks to a number of experienced instrument firms, each of which is principally concerned with the production of a few specific types of optical instruments. In Canada provision had to be made for a completely integrated operation, starting with the raw materials for glass-making and ending with the delivery of twenty-five types of finished instruments.

On September 3, 1940, a start was made in Toronto with two employees. In January 1942 some three thousand optical instruments valued at about £120,000 had been made. The total number of employees was about 3,000, of whom 700 were women, and 100 staff of whom 84 were graduates of Canadian universities. This staff includes 56 graduate engineers, 20 physicists, 3 graduates in engineering physics, and 5 chemists. Research Enterprises Ltd., is, however, much more than a factory for the production of optical instruments alone. In November 1940 a demand was made for the production of various secret devices, and in point of fact the greater part of Research Enterprises Ltd. is concerned with these rather than with optical instruments.

It was immediately realized that if Research Enterprises Ltd. was to produce optical glass in a reasonable time, the best use would have to be made of existing knowledge and experience, and after a thorough study of the records of the difficulties met by the Americans in 1918, it was decided to follow the successful methods of Chance Brothers and Co. Ltd., of Great Britain. Arrangements were made with them in November 1940 to make available to Research Enterprises Ltd. every detail in connexion with the manufacture of optical glass, and personnel sent over from Canada were trained in the British factory; also, certain staff for the Canadian factory were recruited in Great Britain. It speaks well for the co-operation that existed to learn that the first melt was made on June 5, 1941, some seven months after the discussions were inaugurated between the two companies. The production of optical glass in the factory was some 12,500 lb. per month by January 1942, and with additional furnaces coming into operation it is estimated that the monthly yield should be 20,000 lb. of usable glass.

Of the actual production of optical instruments Colonel Phillips said little, but he indicated that the very serious difficulties that were met in the early days of the production had virtually been overcome by the beginning of this year. In the second week of January this year, for example, more than eight thousand individually finished polished optical components were turned out, and the rejection was less than 14 per cent.

The whole story is encouraging, and demonstrates how much can be accomplished if the urgency is sufficiently great and the desire to co-operate sufficiently emphasized.

PLEISTOCENE CLIMATES IN KENYA AND ABYSSINIA

By P. E. KENT

During the last few months the account by Erik Nilsson of his 1932–33 expedition to East Africa has become available in Great Britain[1]. In the course of this, Nilsson describes the continuation of his geological work in central Kenya, and a journey northwards to Abyssinia to extend the scope of the work and obtain comparative data in the more northerly section of the Rift Valley. The results obtained were of considerable interest. High-level beaches which were found in inland drainage basins proved to correspond closely with those known in detail in Kenya, and tuffaceous lacustrine deposits closely similar to those of the Lower-Middle Pleistocene of Kenya were located. Nilsson was also able to find and map moraines and other signs of past glaciation in two regions on the mountain masses.

Nilsson describes first his work in the Nakuru-Naivasha section of the Kenya rift valley, which began in 1927 with a period of collaboration with L. S. B. Leakey, and he claims to have been originally responsible for the recognition of the alternating wet and dry periods during the Upper Pleistocene, which have been related to an archæological time-scale by Leakey and further worked on by Solomon. There have been differences of opinion as to whether or not the older beaches in this basin have been tilted, and it may be commented that on the face of it the levels of shore-lines shown in Nilsson's diagrams (loc. cit., Figs. 18 and 19) appear capable of correlation in ways other than that shown, and do not seem clearly to establish evidence of tilting.

One of the most interesting references in the section of the paper dealing with Kenya is to the discovery by Leakey in 1932 of Stone Age implements in tuffaceous beds on a fault step and at the summit of the scarp forming the eastern wall of the Kenya Rift. Nilsson's opinion that there is no reason to doubt that the containing beds were true "Kamasian" and earlier than the rift faulting—which must, accordingly, be largely later than Middle Pleistocene—was endorsed by Dr. T. T. Paterson and the reviewer when shown the localities by Leakey in 1935. Evidence of recent movement of the Rift Valley faults has been obtained also in Uganda[2] and northern Tanganyika[3].

Nilsson leaves open the question of whether the Lower-Middle Pleistocene "Kamasian" beds of Kenya were laid down in a single lake (as Leakey[4] held) or in a series of lakes aligned along the Rift Valley, although he inclines towards the former. There is much evidence, however, that the uplift which raised East Africa from a low-lying peneplain to an area of high plateaux had been taking place throughout the Tertiary period, and it seems out of the question that a continuous sheet of water can have extended from Lake Rudolf to the summit of the uplift as recently as the late Lower Pleistocene.

In Abyssinia Nilsson first investigated the history of the Shala-Zwai inland drainage basin, situated in the Rift Valley about 75 miles south of Addis Ababa. The basin now contains four salty lakes, but high-level beaches cut into older Pleistocene lacustrine beds show that during the Upper Pleistocene the water-level was up to 150 metres higher, and the separate lakes united in a single, much greater sheet of water over a relatively long period. An extension within very recent times is shown (as in Kenya) by numerous dead trees near the lake shore, 'drowned' by a period of higher water-level.

Lake Tana, the source of the Blue Nile, was found to have owed its origin to damming by lava flows during the last inter-pluvial period, and the sequence of high-level beaches can be correlated in detail with that of the Zwai-Shala and Nakuru-Naivasha basins, but sediments earlier than the Upper Pleistocene are absent. East and south of Debra Markos, however, the Blue Nile flows across an area of the older sediments, named by Nilsson Lake Yaya from the locality of best development. From lithological characters and degree of denudation the beds are provisionally dated as Lower Pleistocene, although faunal evidence of age has yet to be obtained.

Nilsson's comparison of the histories of the Abyssinian lakes with those of Kenya and with the Faiyum depression of Egypt shows a good degree of correspondence. It is, however, based on the number and degree of intensity of wet periods, and the more positive evidence provided by archæological or palæontological dating would be desirable for confirmation of the correlation.

In continuation of his work on the history of glaciation of the mountains of Kenya, Nilsson investigated the largest of the denuded volcanic mountains hich stud the high plateau of Abyssinia. He first sited Mounts Kaka and Chillalo, south-east of ddis Ababa, finding well-developed moraine ridges xtending in the latter case almost 800 metres below he 4,100-metre summit, and he then travelled northrds across the Hawash valley to the Highlands of nien, which lie on the northern edges of the yssinian plateau. On the highest three peaks of ne worn-down volcano forming these highlands he gain discovered extensive moraines and fresh-looking cirques, and shorter moraine ridges formed during the later stages of declining glaciation. Correlation of new data from Abyssinia with the results tained on Kilimanjaro in Tanganyika, Mounts nya and Elgon in Kenya, leads Nilsson to the nclusion that the maximum extension and stages f recession of the mountain glaciers were simultaneous throughout East Africa.

Nilsson's second expedition is hence notable for the great area covered and for the further demonstration that the climatic history of East Africa is not purely local. Thus parallel phenomena are found over a very wide area, and there is a considerable degree of agreement with the standard successions of the Nile Valley and Mediterranean.

THERMAL BREAKDOWN IN SUPER-TENSION CABLES

AN article by E. A. Beavis (Eng. Supp. *Siemens Magazine*, Nos. 202 and 203, March and April, 942) considers the various factors contributing to le failures in the sphere of dielectric heating. ny type of high-voltage cable installation there finite limit to the heat which can be dissipated, ve which the condition of the cable insulation thermally unstable. The chief factor governability is the dielectric loss, which has a critical value dependent partly upon the l constants of the cable but chiefly upon the al thermal conditions. When this value is d, cable breakdown becomes inevitable in urse of time, provided such conditions continue unchanged. This maximum value of dielectric loss, which denotes the commencement of instability, remains constant for a given set of thermal values, and the higher the applied voltage the lower is the critical temperature at which this loss occurs, since it increases as the square of the voltage. For the same conditions, therefore, the higher the voltage the shorter the time required for thermal breakdown to occur. Failure will normally take place when the mperature of the insulation has reached the point which the existing potential gradient exceeds the dielectric strength, and in most cases will occur shortly after passing the critical value.

For very high voltages, failure in some cases precedes the actual approach of instability by reason of educed dielectric strength consequent upon the high able temperature attained, and conversely with omparatively low voltages the time to breakdown ay occasionally be much prolonged on account of a dielectric loss/temperature characteristic reducing te of temperature rise. Should the thermal conditions change in such a way that the temperature tends to fall again below the critical point before breakdown takes place, then thermal failure will in general be avoided. In the case of super-tension cables of special design where ionization is suppressed, no permanent deterioration may take place under the above conditions, but with the normal sc [illegible] type cables distortion of the lead sheath will o [illegible] due to excessive expansion of the cable oil, tending to produce ionization on cooling which will probably render the cable unfit for service in course of ti [illegible]

On account of the increase in dielectric loss, the higher the applied voltage the less the thermal factor of safety for the same maximum conductor temperature. As it is often necessary for economical reasons to run the highest voltage cables at their maximum permissible temperature, it becomes essential to study carefully the thermal conditions for such installations in order to ascertain the limiting current-carrying capacity of the cable. Although it is now possible to calculate the thermal characteristics for any cable reasonably accurately from published data, it is customary to carry out special testing operations on short lengths of about thirty yards of various types of super-tension cable in the high-voltage laboratory. Such tests, usually denoted as stability tests, consist in running a series of loading [illegible]es on the cable conductors with superimposed v [illegible] ge, so as to simulate so far as possible the conditions in practice. Extending these tests by gradually increasing current and voltage on periodic cycles until thermal breakdown ensues enables the limits of thermal stability to be ascertained for the given conditions. Such tests are usually carried out in air with the cable laid out on the test house floor, the ends being properly terminated in porcelain insulators. From the results it is possible to calculate the critical temperature for any particular t [illegible] l condition, thus providing an indication of [illegible] hermal factor of safety in the given circumst [illegible]

For the purpose of calculating the [illegible]rmal breakdown phenomena the author shows the development of some of the heating formulæ which have been published earlier. These are dealt with under the headings of cable heating due to load current, and dielectric loss heating. Test results are given for various sizes and types of single- and three-core cables from 33 kv. to 132 kv. The examples show that, with accurate thermal data, it [illegible] possible to calculate the time/temperature e [illegible] reasonably closely and to predict the minimu [illegible] robable time for thermal breakdown, since this pra [illegible] ically approximates to the attainment of the critical temperature. Although in theory the cable may be thermal [illegible] stable up to this point, the actual va [illegible] of the dielectric loss is of no real practical significance, as [illegible] would be impossible for the cable to withstand such high temperature for long. However, the importance of the dielectric loss temperature coefficient and of the thermal resistance—mainly the external part, since the cable itself remains more or less constant—is definitely established with regard to thermal stability under working conditions. Since the critical temperature depends primarily upon these two characteristics, the ratio of critical temperature to working temperature can be looked upon as the thermal safety factor. It is evident that with high-voltage cables the relation between dielectric loss and temperature needs to be studied carefully in order that full allowance can be made for all the thermal factors of the installation.

[illegible]ANSFORMER NOISE

A PAPER by J. Swaffield (*J. Inst. Elec. Eng.*, 89, Pt. 1, No. 17, May, 1942) reports the main results of an investigation carried out (1935–37) by the British Electrical and Allied Industries Research Association on model cores under controlled conditions to provide fundamental information on transformer noise. The factors affecting core noise are flux density, magnitude and uniformity of the core clamping pressure, steel quality, lamination thickness, type and thickness of interlaminar insulation, and method of interleaving the laminations. The ranges of design variables covered by the tests were flux density, 8,000–16,000 lines/cm.² or higher; clamping pressure, 0–350 lb./sq. in.; qualities of steel, *E.S.* stalloy and stalloy; thickness of laminations, 14 and 18 mils; insulation between laminations, insuline, paper and scale only; type of joint, concentrated, distributed and none.

At 50 c./s. excitation, the noise was found to consist of 100 c./s. harmonics of which the 200 c./s. and 300 c./s. components usually predominated; no 50 c./s. harmonics were present. Noise is associated with the following fundamental sources of vibration: interlaminar fluxes, resulting in vibration of individual laminations; magnetostriction, resulting primarily in core vibration as a whole; forces between turns due to winding currents, resulting primarily in conductor vibration. The effects of the various factors upon emitted noise were found to be those now cited.

Harmonic intensity levels are all functions of flux density, which greatly influences noise quality and quantity. Clamping affects only the joint noise, which can be determined only by experiment; if it forms an appreciable proportion of the total, joint noise becomes important, as it is penetrating. The effects of joint noise appear to be present mainly in the noise emission at 400 c./s. and higher frequencies. Joint [illegible] be reduced greatly by careful core assembly, including interleaving. Very large clamping pressures are unnecessary and it is more important that the clamping should be effective in the region of a joint than large at any particular point. Immersion in oil has a considerable effect in suppressing joint noise. Great reduction in the core vibration combined with reasonable economy is not to be anticipated unless the magnetostriction effect is reduced, and only by a suitable modification in its magnetostrictive property can a change in the type of steel be expected to effect an improvement in noise emission. Thickness of stampings affects only the joint noise and is unimportant. The insulation used between stampings does not appreciably affect the noise. Interleaving, in conjunction with suitable clamping, tends to effect substantial reduction in joint noise. Noise contributed by the coils consists mainly of fundamental tone and is not generally important compared with core noise.

The noise emitted by a transformer is thus due mostly to magnetostriction in the core laminations and to core joints. In large transformers the effect of magnetostriction predominates, but in smaller units the joints may effect substantial modification of the noise caused by magnetostriction. The main characteristics of magnetostrictive noise can be calculated by determining the form of the vibration it induces in the core and analysing this to obtain a measure of the sound intensity at the various harmonic frequencies. Experiments on model cores showed that results so obtained are representative of the noise actually produced. Improvement can be effected by reducing the flux density, but this is not economical. In order to secure a perfectly quiet transformer both joint noise and magnetostriction noise must be eliminated. As the latter predominates in all but the smallest transformers, little improvement can be expected by reducing the former.

Since the main investigation was carried out, a series of noise-analysis measurements has been made on a commercial transformer in an oil-filled tank and in air. Apart from joint noise the tests indicated that oil-immersion of the core has little effect on the characteristics of the noise. Both series of harmonic analyses showed remarkable similarities to those given in the report; such results as were obtained all tended to confirm the conclusions reached by the investigator.

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

ASSISTANT CHIEF ELECTRICAL ENGINEER to the Letchworth Electricity Undertaking—The Chief Electrical Engineer, Electricity Works, Letchworth (July 2).

ASSISTANT DAIRY BACTERIOLOGIST—The Bursar, Seale-Hayn Agricultural College, Newton Abbot, Devon (July 4).

EDUCATIONAL PSYCHOLOGIST (MAN OR WOMAN)—The City Educatio Officer, 12 St. Giles Street, Edinburgh 1 (July 4).

LECTURER IN ENGINEERING SUBJECTS—The Principal, Kingsto Technical College, Kingston, Surrey (July 4).

FIRST ENGINEERING ASSISTANT in the Waterworks Department of the County Borough of Brighton—The Waterworks Engineer, 12 Bon Street, Brighton (endorsed 'First Engineering Assistant') (July 6).

PRINCIPAL OF THE BATLEY TECHNICAL COLLEGE AND SCHOOL OF ART—The Director of Education and Secretary to the Managers Batley Technical College and School of Art, Batley, Yorkshire (July 6

TECHNICAL ASSISTANT in the Electricity Department of the County Borough of Londonderry—The Town Clerk, Guildhall, Londonderr (July 7).

LECTURER IN ZOOLOGY (MAN OR WOMAN)—The Registrar, Universit College, Leicester (July 13).

ASSISTANT DAIRY BACTERIOLOGIST—The Principal, Harper A Agricultural College, Newport, Shropshire.

WOMAN LECTURER IN GEOGRAPHY—The Principal, Edge Hil ing College, at Bingley, Yorkshire.
